$$\chi_{\delta\gamma}^\Delta = \frac{e^2}{4m_e^2 c^2 \hbar} \epsilon_{\alpha\beta\gamma} \sum_{j \neq a} \omega_{ja}^{-1} \left\{ \langle a | \sum_{i=1}^n [(r_\beta - r'_\beta) \hat{I}_\delta]_i | j \rangle \langle j | \hat{P}_\alpha | a \rangle \right. \\ \left. + \langle a | \hat{P}_\alpha | j \rangle \langle j | \sum_{i=1}^n [(r_\beta - r'_\beta) \hat{I}_\delta]_i | a \rangle \right\} \quad (106)$$

$$\sigma_{\delta\gamma}^{\Delta I} = -\frac{e^2}{2m_e^2 c^2 \hbar} \epsilon_{\alpha\beta\gamma} \sum_{j \neq a} \omega_{ja}^{-1} \left\{ \langle a | \sum_{i=1}^n (r_{i\beta} - r'_{i\beta}) \hat{M}_{I\delta} | j \rangle \langle j | \hat{P}_\alpha | a \rangle \right. \\ \left. + \langle a | \hat{P}_\alpha | j \rangle \langle j | \sum_{i=1}^n (r_{i\beta} - r'_{i\beta}) \hat{M}_{I\delta} | a \rangle \right\} \quad (107)$$

which reduce to the conventional diamagnetic contributions, equation (74) in the limit of complete basis sets.

3.5 Sum Rules for Origin Independence

The total theoretical magnetic properties of a molecule in a spatially uniform and time-independent magnetic field must be independent of the origin of the coordinate system. In a change of gauge, equation (33), of the Coulomb vector potential, variations of diamagnetic and paramagnetic contributions should cancel each other exactly. The constraints for invariance are expressed via auxiliary tensors

$$(\hat{P}_\alpha, \hat{L}_\beta)_{-1} = \frac{1}{\hbar} \sum_{j \neq a} \frac{2}{\omega_{ja}} \operatorname{Re}(\langle a | \hat{P}_\alpha | j \rangle \langle j | \hat{L}_\beta | a \rangle) \quad (108)$$

$$(\hat{K}_{n\alpha}^N, \hat{P}_\beta)_{-2} = -\frac{1}{\hbar} \sum_{j \neq a} \frac{2}{\omega_{ja}^2} \operatorname{Im}(\langle a | \hat{K}_{n\alpha}^N | j \rangle \langle j | \hat{P}_\beta | a \rangle) \quad (109)$$

$$(\hat{F}_{n\alpha}^N, \hat{L}_\beta)_{-2} = -\frac{1}{\hbar} \sum_{j \neq a} \frac{2}{\omega_{ja}^2} \operatorname{Im}(\langle a | \hat{F}_{n\alpha}^N | j \rangle \langle j | \hat{L}_\beta | a \rangle) \quad (110)$$

$$(\hat{F}_{n\alpha}^N, \hat{K}_{n\beta}^N)_{-3} = \frac{1}{\hbar} \sum_{j \neq a} \frac{2}{\omega_{ja}^3} \operatorname{Re}(\langle a | \hat{F}_{n\alpha}^N | j \rangle \langle j | \hat{K}_{n\beta}^N | a \rangle) \quad (111)$$

$$(\hat{P}_\alpha, \hat{P}_\beta)_{-1} = \frac{1}{\hbar} \sum_{j \neq a} \frac{2}{\omega_{ja}} \operatorname{Re}(\langle a | \hat{P}_\alpha | j \rangle \langle j | \hat{P}_\beta | a \rangle) \quad (112)$$

$$(\hat{F}_{n\alpha}^N, \hat{P}_\beta)_{-2} = -\frac{1}{\hbar} \sum_{j \neq a} \frac{2}{\omega_{ja}^2} \operatorname{Im}(\langle a | \hat{F}_{n\alpha}^N | j \rangle \langle j | \hat{P}_\beta | a \rangle) \quad (113)$$

$$(\hat{F}_{n\alpha}^N, \hat{F}_{n\beta}^N)_{-3} = \frac{1}{\hbar} \sum_{j \neq a} \frac{2}{\omega_{ja}^3} \operatorname{Re}(\langle a | \hat{F}_{n\alpha}^N | j \rangle \langle j | \hat{F}_{n\beta}^N | a \rangle) \quad (114)$$

$$(\hat{P}_\alpha, \hat{M}_{I\beta}^n)_{-1} = \frac{1}{\hbar} \sum_{j \neq a} \frac{2}{\omega_{ja}} \text{Re}(\langle a | \hat{P}_\alpha | j \rangle \langle j | \hat{M}_{I\beta}^n | a \rangle) \quad (115)$$

$$(\hat{F}_{n\alpha}^N, \hat{M}_{I\beta}^n)_{-2} = -\frac{1}{\hbar} \sum_{j \neq a} \frac{2}{\omega_{ja}^2} \text{Im}(\langle a | \hat{F}_{n\alpha}^N | j \rangle \langle j | \hat{M}_{I\beta}^n | a \rangle) \quad (116)$$

with the property $(\hat{X}, \hat{Y})_{-q} = (\hat{Y}, \hat{X})_{-q}$. Corresponding to different origins,

$$\begin{aligned} \chi_{(LL)\alpha\beta}^p(\mathbf{r}'') &= \chi_{(LL)\alpha\beta}^p(\mathbf{r}') + \frac{e^2}{4m_e^2 c^2} \{d_\delta [\epsilon_{\alpha\gamma\delta} (\hat{P}_\gamma, \hat{L}_\beta(\mathbf{r}'))_{-1} \\ &\quad + \epsilon_{\beta\gamma\delta} (\hat{P}_\gamma, \hat{L}_\alpha(\mathbf{r}'))_{-1}] \\ &\quad + \epsilon_{\alpha\gamma\delta} \epsilon_{\beta\lambda\mu} d_\delta d_\mu (\hat{P}_\gamma, \hat{P}_\lambda)_{-1}\} \end{aligned} \quad (117)$$

$$\begin{aligned} \chi_{(KL)\alpha\beta}^p(\mathbf{r}'') &= \chi_{(KL)\alpha\beta}^p(\mathbf{r}') + \frac{e^2}{4m_e^2 c^2} \{d_\delta [\epsilon_{\alpha\gamma\delta} (\hat{F}_{n\gamma}^N, \hat{L}_\beta(\mathbf{r}'))_{-2} \\ &\quad + \epsilon_{\beta\gamma\delta} (\hat{P}_\gamma, \hat{K}_{n\alpha}^N(\mathbf{r}'))_{-2}] \\ &\quad + \epsilon_{\alpha\gamma\delta} \epsilon_{\beta\lambda\mu} d_\delta d_\mu (\hat{F}_{n\gamma}^N, \hat{P}_\lambda)_{-2}\} \end{aligned} \quad (118)$$

$$\begin{aligned} \chi_{(KK)\alpha\beta}^p(\mathbf{r}'') &= \chi_{(KK)\alpha\beta}^p(\mathbf{r}') + \frac{e^2}{4m_e^2 c^2} \{d_\delta [\epsilon_{\alpha\gamma\delta} (\hat{F}_{n\gamma}^N, \hat{K}_{n\beta}^N(\mathbf{r}'))_{-3} \\ &\quad + \epsilon_{\beta\gamma\delta} (\hat{F}_{n\gamma}^N, \hat{K}_{n\alpha}^N(\mathbf{r}'))_{-3}] \\ &\quad + \epsilon_{\alpha\gamma\delta} \epsilon_{\beta\lambda\mu} d_\delta d_\mu (\hat{F}_{n\gamma}^N, \hat{F}_{n\lambda}^N)_{-3}\} \end{aligned} \quad (119)$$

$$\begin{aligned} \chi_{\alpha\beta}^d(\mathbf{r}'') &= \chi_{\alpha\beta}^d(\mathbf{r}') + \frac{e^2}{4m_e c^2} [2\langle a | \hat{R}_\gamma(\mathbf{r}') | a \rangle d_\gamma \delta_{\alpha\beta} - \langle a | \hat{R}_\alpha(\mathbf{r}') | a \rangle d_\beta \\ &\quad - \langle a | \hat{R}_\beta(\mathbf{r}') | a \rangle d_\alpha - n d_\gamma d_\gamma \delta_{\alpha\beta} + n d_\alpha d_\beta] \end{aligned} \quad (120)$$

$$\sigma_{(L)\alpha\beta}^{pI}(\mathbf{r}'') = \sigma_{(L)\alpha\beta}^{pI}(\mathbf{r}') - \frac{e^2}{2m_e^2 c^2} \epsilon_{\beta\gamma\delta} d_\delta (\hat{M}_{I\alpha}^n, \hat{P}_\gamma)_{-1} \quad (121)$$

$$\sigma_{(K)\alpha\beta}^{pI}(\mathbf{r}'') = \sigma_{(K)\alpha\beta}^{pI}(\mathbf{r}') - \frac{e^2}{2m_e^2 c^2} \epsilon_{\beta\gamma\delta} d_\delta (\hat{M}_{I\alpha}^n, \hat{F}_{n\gamma}^N)_{-2} \quad (122)$$

$$\sigma_{\alpha\beta}^{dI}(\mathbf{r}'') = \sigma_{\alpha\beta}^{dI}(\mathbf{r}') - \frac{e}{2m_e c^2} (d_\gamma \langle \hat{E}_{I\gamma}^n \rangle \delta_{\alpha\beta} - d_\alpha \langle \hat{E}_{I\beta}^n \rangle) \quad (123)$$

Therefore the sum rules for translational invariance of total susceptibility and nuclear magnetic shielding are

$$\begin{aligned} (\hat{P}_\alpha, \hat{L}_\beta)_{-1} &= (\hat{K}_{n\alpha}^N, \hat{P}_\beta)_{-2} = (\hat{F}_{n\alpha}^N, \hat{L}_\beta)_{-2} = (\hat{F}_{n\alpha}^N, \hat{K}_{n\beta}^N)_{-3} \\ &= m_e \epsilon_{\alpha\beta\gamma} \langle a | \hat{R}_\gamma | a \rangle \end{aligned} \quad (124)$$

$$(\hat{P}_\alpha, \hat{M}_{I\beta}^n)_{-1} = (\hat{F}_{n\alpha}^N, \hat{M}_{I\beta}^n)_{-2} = \frac{m_e}{e} \epsilon_{\alpha\beta\gamma} \langle a | \hat{E}_{I\gamma}^n | a \rangle \quad (125)$$

$$(\hat{P}_\alpha, \hat{P}_\beta)_{-1} = (\hat{F}_{n\alpha}^N, \hat{P}_\beta)_{-2} = (\hat{F}_{n\alpha}^N, \hat{F}_{n\beta}^N)_{-3} = m_e n \delta_{\alpha\beta} \quad (126)$$

These formulas can also be directly established from equations (65) and (66) and from the integral condition for charge conservation, equation (77), i.e., the necessary condition for gauge invariance (cf. equation (23)).

For a transformation, equation (44), in the Landau gauge, one finds for the magnetic susceptibility and shielding of nucleus I ,

$$\begin{aligned} \chi_{xx}^{dL}(\mathbf{r}'') &= \chi_{xx}^{dL}(\mathbf{r}') + \frac{e^2}{m_e c^2} \\ &\quad \times \left[2\langle a | \sum_{i=1}^n (y_i - y') | a \rangle d_y - n d_y^2 \right] \end{aligned} \quad (127a)$$

$$\begin{aligned} \chi_{xx}^{pL}(\mathbf{r}'') &= \chi_{xx}^{pL}(\mathbf{r}') - \frac{e^2}{m_e^2 c^2} \\ &\quad \times [2(\hat{T}_x, \hat{P}_z)_{-1} d_y - (\hat{P}_z, \hat{P}_z)_{-1} d_y^2] \end{aligned} \quad (127b)$$

$$\begin{aligned} \chi_{xy}^{pL}(\mathbf{r}'') &= \chi_{xx}^{pL}(\mathbf{r}') - \frac{e^2}{m_e^2 c^2} [(\hat{T}_x, \hat{P}_x)_{-1} d_z + (\hat{T}_y, \hat{P}_z)_{-1} d_y \\ &\quad - (\hat{P}_z, \hat{P}_x)_{-1} d_y d_z] \end{aligned} \quad (127c)$$

$$\sigma_{xx}^{dIL}(\mathbf{r}'') = \sigma_{xx}^{dIL}(\mathbf{r}') - \frac{e}{m_e c^2} \langle a | \hat{E}_{Iy}^n | a \rangle d_y \quad (128a)$$

$$\sigma_{xx}^{pIL}(\mathbf{r}'') = \sigma_{xx}^{pIL}(\mathbf{r}') + \frac{e^2}{m_e^2 c^2} (\hat{M}_{Ix}^n, \hat{P}_z)_{-1} d_y \quad (128b)$$

$$\sigma_{yx}^{dIL}(\mathbf{r}'') = \sigma_{yx}^{dIL}(\mathbf{r}') + \frac{e}{m_e c^2} \langle a | \hat{E}_{Ix}^n | a \rangle d_y \quad (128c)$$

$$\sigma_{yx}^{pIL}(\mathbf{r}'') = \sigma_{yx}^{pIL}(\mathbf{r}') + \frac{e^2}{m_e^2 c^2} (\hat{M}_{Iy}^n, \hat{P}_z)_{-1} d_y \quad (128d)$$

$$\sigma_{xy}^{pIL}(\mathbf{r}'') = \sigma_{xy}^{pIL}(\mathbf{r}') + \frac{e^2}{m_e^2 c^2} (\hat{M}_{Ix}^n, \hat{P}_x)_{-1} d_z \quad (128e)$$

Therefore additional conditions for the invariance of theoretical Landau susceptibility under a coordinate transformation are

$$\begin{aligned} (\hat{P}_z, \hat{T}_x)_{-1} &= m_e \langle a | \sum_{i=1}^n (y_i - y') | a \rangle \\ (\hat{P}_z, \hat{T}_y)_{-1} &= (\hat{T}_x, \hat{P}_x)_{-1} = 0 \end{aligned} \quad (129)$$

$$(\hat{T}_z, \hat{P}_y)_{-1} = \frac{1}{\hbar} \sum_{j \neq a} \frac{2}{\omega_{ja}} \text{Re} \left\{ \langle a | \sum_{i=1}^n [(x - x') \hat{p}_y]_i | j \rangle \langle j | \hat{P}_y | a \rangle \right\} \quad (130)$$

The diamagnetic terms in propagator form change according to

$$\begin{aligned} \chi_{\delta\gamma}^\Delta(\mathbf{r}'') &= \chi_{\delta\gamma}^\Delta(\mathbf{r}') - \frac{e^2}{4m_e^2 c^2} \epsilon_{\alpha\beta\gamma} \\ &\quad \times \left\{ d_\beta (\hat{P}_\alpha, \hat{L}_\delta)_{-1} - d_\beta d_\lambda \epsilon_{\delta\lambda\mu} (\hat{P}_\alpha, \hat{P}_\mu)_{-1} \right. \\ &\quad + \hbar^{-1} d_\lambda \epsilon_{\delta\lambda\mu} \sum_{j \neq a} \omega_{ja}^{-1} \left[\langle a | \sum_{i=1}^n (r_{i\beta} - r'_{\beta}) \hat{p}_{i\mu} | j \rangle \langle j | \hat{P}_\alpha | a \rangle \right. \\ &\quad \left. \left. + \langle a | \hat{P}_\alpha | j \rangle \langle j | \sum_{i=1}^n (r_{i\beta} - r'_{\beta}) \hat{p}_{i\mu} | a \rangle \right] \right\} \end{aligned} \quad (131)$$

$$\sigma_{\delta\gamma}^{\Delta I}(\mathbf{r}'') = \sigma_{\delta\gamma}^{\Delta I}(\mathbf{r}') + \frac{e^2}{2m_e^2 c^2} \epsilon_{\alpha\beta\gamma} d_\beta (\hat{P}_\alpha, \hat{M}_{I\delta}^n)_{-1} \quad (132)$$

In the limit of exact variational wavefunctions, equations (131) and (132) are the same as equations (120) and (123) for the conventional diamagnetic contributions. From equations (117) and (131), one can see that the total susceptibility $\chi_{(LL)\alpha\beta}^p + \chi_{\alpha\beta}^\Delta$ depends only linearly on $\mathbf{d}$ also within the algebraic

approximation, owing to exact cancellation of quadratic terms: the constraint for translational invariance becomes

$$\begin{aligned}
 (\hat{P}_\mu, \hat{L}_\gamma)_{-1} &= -\frac{1}{\hbar} \epsilon_{\alpha\beta\gamma} \sum_{j \neq a} \omega_{ja}^{-1} \\
 &\times \left\{ \langle a | \sum_{i=1}^n [(r_\beta - r'_\beta) \hat{p}_\mu]_i | j \rangle \langle j | \hat{P}_\alpha | a \rangle \right. \\
 &\left. + \langle a | \hat{P}_\alpha | j \rangle \langle j | \sum_{i=1}^n [(r_\beta - r'_\beta) \hat{p}_\mu]_i | a \rangle \right\} \quad (133)
 \end{aligned}$$

which is equivalent to equation (108), as shown by the first hypervirial relation, equation (65). For some molecules, quantities appearing in equation (133) vanish by symmetry (e.g., if there is a center of inversion) and the total susceptibility from equations (117) and (131) is origin-independent also in the algebraic approximation.

It is also worthy of notice, in calculations using finite basis sets and irrespective of symmetry, that all of the total shielding tensor components $\sigma_{(L)\alpha\beta}^{PI} + \sigma_{\alpha\beta}^{\Delta I}$ are independent of the origin, since there is exact cancellation between paramagnetic and Δ contributions (cf. equations (121) and (132)).

1 INTRODUCTION

In an NMR experiment, the magnetic field $\mathbf{B}$ at the nucleus differs from the applied magnetic field $\mathbf{B}_0$. In the absence of medium effects, this magnetic field difference is due to the shielding of the nucleus by the electrons in the molecule. In chemically different molecules, the electronic structures vary; consequently, the chemical shielding of a nucleus depends upon the nature of its electronic environment. The relationship between $\mathbf{B}$ and $\mathbf{B}_0$ is given by

$$\mathbf{B} = (\mathbf{1} - \boldsymbol{\sigma})\mathbf{B}_0 \quad (1)$$

where $\boldsymbol{\sigma}$ is the second-rank chemical shielding tensor.

Experimentally, the term ‘chemical shift’ is often used in preference to ‘chemical shielding’. The chemical shift δ_X of a nucleus X with respect to a given standard is given by

$$\delta_X = \sigma_{\text{std}} - \sigma_X \quad (2)$$

Consequently, an increase in shielding corresponds to a decrease in chemical shift, and vice versa.

In principle, the effects of chemical shielding can take either sign. A positive value of σ results in an increase in chemical shielding, sometimes referred to as a diamagnetic effect. Alternatively, deshielding occurs if σ is negative; this corresponds to a paramagnetic effect.

In general, $\boldsymbol{\sigma}$ is an unsymmetric second-rank tensor, namely $\sigma_{ij} \neq \sigma_{ji}$. In contrast with experiment, theoretical calculations provide values for all of the tensor components. The tensor is usually decomposed into its symmetric, $\boldsymbol{\sigma}^s$, and antisymmetric, $\boldsymbol{\sigma}^a$, components for the purposes of comparison with experimental data:

$$\sigma_{ij}^s = \frac{1}{2}(\sigma_{ij} + \sigma_{ji}) \quad (3)$$

$$\sigma_{ij}^a = \frac{1}{2}(\sigma_{ij} - \sigma_{ji}) \quad (4)$$

In the expression that describes the interactions between a molecule and an applied magnetic field, σ_{ij}^a only appears in terms which are second order in the magnetic field. Thus, the effects of σ_{ij}^a are not normally observed in standard NMR experiments, which depend upon interactions that are first order with respect to the applied magnetic field. Consequently, the calculated values of σ_{ij}^a are neglected, and

the diagonalization of σ_{ij}^s results in the determination of the principal axes of the shielding tensor. The isotropic shielding σ_{av} , the shielding anisotropy $\Delta\sigma$, and the asymmetry ξ are then determined from the diagonal elements, σ_{11} , σ_{22} , and σ_{33} , where the usual convention is $\sigma_{11} \leq \sigma_{22} \leq \sigma_{33}$, as follows:

$$\sigma_{\text{av}} = \frac{1}{3}(\sigma_{11} + \sigma_{22} + \sigma_{33}) \quad (5)$$

$$\Delta\sigma = \sigma_{33} - \frac{1}{2}(\sigma_{11} + \sigma_{22}) \quad (6)$$

$$\xi = \frac{\sigma_{22} - \sigma_{11}}{\sigma_{33} - \sigma_{\text{av}}} \quad (7)$$

From NMR studies on nonviscous liquids, only values of σ_{av} are available for comparison with calculation. However, in the case of aligned molecules such as those in solids or liquid crystals, NMR measurements can provide information on $\Delta\sigma$ and ξ . It should be noted that, in general, the errors in experimental results for $\Delta\sigma$ and ξ are larger than in those for σ_{av} .

2 BASIC THEORETICAL CONSIDERATIONS

In principle, quantum mechanics can produce a full account of all molecular properties. In practice, various approximations are introduced into the calculations to make them tractable. Such approximations produce apodictic limitations on the results obtained. For example, Hartree–Fock (HF) level calculations, involving a single determinant, on rigid isolated molecules ignore the effects of electron correlation, variations of geometry, and media influences on chemical shielding. Normally, such effects are considered separately, as are possible relativistic effects on the shielding of heavier nuclei. Another aspect of theoretical calculations is the requirement of a specified molecular geometry—often, precise experimental geometries are unknown, in which case quantum mechanics can provide a minimum energy or ‘optimized’ structure. In practice, such calculations tend to be restricted to small and medium sized molecules. Structural information obtained from HF calculations is usually fairly reliable. The agreement with experimental bond lengths is normally within 1–3 pm and the bond angles usually differ by less than 2° or 3°.¹ The results obtained from ab initio molecular orbital calculations often depend upon the choice of basis set used. For reliable results, the calculation should be convergent with respect to the choice of basis set. The preceding comments in this section apply to calculations of all molecular electronic properties. Calculations of magnetic properties, such as chemical shielding, suffer from an additional limitation. This is known as the gauge problem. It arises from the use of perturbation theory to describe the, rather small, contribution to the total electronic energy of the molecule provided by the applied magnetic field. The magnetic perturbation is described by means of the orbital angular momentum operator. Since this operator is not invariant with respect to translations, its influence depends upon the position at which it is evaluated. Consequently, the result obtained for the calculated chemical shielding depends upon the choice of origin for the calculation. This is a theoretical artifact, which needs to be dealt with before comparison between experimental and theoretical shielding data occurs.

The first serious attempt to calculate chemical shielding effects was Ramsey's work in 1950.^{2,3} Perturbation theory was used to produce an expression for the elements $\sigma_{\alpha\beta}$ ($\alpha, \beta = x, y, z$) of the shielding tensor in a Cartesian coordinate system (x, y, z):

$$\sigma_{\alpha\beta} = \sigma_{\alpha\beta}^d + \sigma_{\alpha\beta}^{dg} + \sigma_{\alpha\beta}^p + \sigma_{\alpha\beta}^{pg} \quad (8)$$

Here d and p indicate the diamagnetic and paramagnetic components and g indicates the gauge-dependent terms. The diamagnetic terms depend only upon the wavefunction of the electronic ground state, while the paramagnetic expressions involve the wavefunctions of all of the molecular excited states, including those of the continuum. The expressions for the four terms appearing in equation (8) are as follows:

$$\sigma_{\alpha\beta}^d = \frac{\mu_0 e^2}{8\pi m} \langle 0 | \sum_k \frac{r_k^2 \delta_{\alpha\beta} - r_{k\alpha} r_{k\beta}}{r_k^3} | 0 \rangle \quad (9)$$

$$\sigma_{\alpha\beta}^{dg} = \frac{\mu_0 e^2}{8\pi m} \langle 0 | \sum_k \frac{R_\alpha r_{k\beta} - R_\gamma r_{k\gamma} \delta_{\alpha\beta}}{r_k^3} | 0 \rangle \quad (10)$$

$$\sigma_{\alpha\beta}^p = \frac{\mu_0 e^2}{8\pi m^2} \sum_r' \frac{1}{E_0 - E_n} \left(\langle 0 | \sum_k \frac{\hat{l}_{k\alpha}}{r_k^3} | n \rangle \langle n | \sum_k \hat{l}_{k\beta} | 0 \rangle + \langle 0 | \sum_k \hat{l}_{k\beta} | n \rangle \langle n | \sum_k \frac{\hat{l}_{k\alpha}}{r_k^3} | 0 \rangle \right) \quad (11)$$

$$\sigma_{\alpha\beta}^{pg} = \frac{\mu_0 e^2}{8\pi m^2} \epsilon_{\beta\gamma\delta} R_\gamma \sum_n' \frac{1}{E_0 - E_n} \left(\langle 0 | \sum_k \frac{\hat{l}_{k\alpha}}{r_k^3} | n \rangle \langle n | \sum_k \hat{p}_{k\delta} | 0 \rangle + \langle 0 | \sum_k \hat{p}_{k\delta} | n \rangle \langle n | \sum_k \frac{\hat{l}_{k\alpha}}{r_k^3} | 0 \rangle \right) \quad (12)$$

Here, μ_0 is the permeability of free space, $\mathbf{r}_k$ is the position vector of electron k with respect to the origin of the Cartesian coordinates, and $\hat{l}_k = \mathbf{r}_k \times \hat{\mathbf{p}}_k$ is the orbital angular momentum operator, with $\hat{\mathbf{p}}$ the linear momentum operator; the primes on the summations over n indicate that the ground state ($n = 0$) is not included, the Kronecker delta $\delta_{\alpha\beta} = 1$ if $\alpha = \beta$ and 0 if $\alpha \neq \beta$; the alternating tensor $\epsilon_{\beta\gamma\delta} = 1$ if $\beta\gamma\delta$ is an even permutation of xyz , -1 if $\beta\gamma\delta$ is an odd permutation of xyz , and 0 if any two of β, γ or δ are identical. In equations (10) and (12), $\mathbf{R}$ is the vector separation between the origin of the Cartesian coordinates and the origin of the vector potential of the applied magnetic field (the gauge origin)

Normally, the shielding is calculated with respect to the origin of the coordinates. Thus, if the nucleus of interest is chosen to be at the gauge origin then $\mathbf{R} = 0$ and the right-hand sides of equations (10) and (12) become zero. Evidently, the appropriate choice of nuclear position in the calculation can lead to the removal of gauge dependence in the theoretical shielding value.

The requirement of knowledge of the energies of all of the molecular electronic excited states, together with the continuum, in order to evaluate equation (11) points to a further drawback to Ramsey's shielding formulation. In general, little is known about the discrete high-energy or the continuum states of most molecules. Some detailed calculations for small molecules imply that shielding contributions from the continuum may be at least as important as those from discrete electronic states.^{4,5}

To be able to calculate chemical shielding reliably on a fairly routine basis, it is necessary to have molecular orbital equivalents of Ramsey's expressions that do not suffer from the gauge problem or the involvement of the continuum states. The coupled Hartree–Fock (CHF) development by Lipscomb⁶ provides the way forward. At present, ab initio molecular orbital (MO) calculations of nuclear shieldings for nuclei from the first and second long rows of the Periodic Table can reproduce experimental data to within about 3 or 4% of an element's shielding range. Consequently, such calculations can be used for predictive purposes as well as providing some information on the molecular electronic factors that determine the extent of nuclear shielding and its variations. Some details of these calculations are considered in the next section.

3 AB INITIO MOLECULAR ORBITAL CALCULATIONS

The electronic shielding of nuclei in molecules is a very small effect when compared with the total electronic energy of a molecule. Thus, very accurate wavefunctions are required to calculate the shielding effect satisfactorily. This, in turn, shows the necessity of using large basis sets in the CHF shielding calculations. Another reason for employing a large basis set is that a complete basis set would provide CHF shielding results that are gauge-independent.⁷ In contrast to this, approximate wavefunctions produce gauge-dependent shielding results unless the gauge origin is taken to be at the nucleus of interest.⁸

3.1 Common Origin Calculations

Large-basis-set calculations, using a common gauge origin, can provide nuclear shieldings in very good agreement with experiment. Table 1 shows the results of some calculations of this type for some small hydrocarbons.^{9,10} The best gauge origin is found to be at the ^{13}C nucleus. The basis sets used include 3d sets for carbon and 2p sets for hydrogen. This choice of basis sets is in agreement with those employed in similar CHF calculations.^{11,12} In general, the choice of an extended basis set is not a practical one for CHF calculations on larger molecules. An example of common origin ^{13}C shielding calculations for a large molecule is provided by C_{60} , buckminsterfullerene. In this molecule, all of the carbons are equivalent, and so symmetry arguments can be used to reduce the number of integrals to be evaluated. ^{13}C shielding results have been obtained using some relatively small basis sets: STO-3G, STO-3G*, 6-31G, and 6-31G*.^{13,14} To obtain some idea of the effort involved in these calculations, we consider the case of using the 6-31G* basis set. This calculation involves 900 orbitals and 8.2×10^{10} two-electron integrals. Symmetry requirements show that about 7×10^8 of these integrals are unique. Further arguments reveal that many of these are sufficiently small to be ignored; however, this leaves about 1.29×10^8 integrals to be evaluated. The cpu time required for this calculation is about 233 h i.e., almost 10 days! With such demands on computational facilities, it is unlikely that common origin shielding calculations will become widespread.

Table 1 Comparison of some Common Origin Calculated and Experimental ^{13}C Shieldings (in ppm)^a

	σ_{xx}	σ_{yy}	σ_{zz}	σ_{au}	Experimental
CH ₄	195.8	195.8	195.8	195.8	195.1
C ₂ H ₆	187.7	182.7	193.1	186.2	180.9
C ₂ H ₄	177.9	-81.1	84.3	60.4	64.5
C ₂ H ₂	39.0	39.0	279.4	119.1	117.2

^aThe unique axis is taken to be the z axis; e.g., in C₂H₄, z is along the C–C bond and x is perpendicular to the molecular plane.

In judging the results of the ^{13}C shielding calculations for C₆₀, it is necessary to appreciate that the basis sets employed are inadequate to obtain convergence of the shielding with respect to the basis set. Additionally, it has to be remembered that these common origin calculations, using incomplete basis sets, will produce shieldings that are gauge-dependent. A selection of the results obtained for C₆₀ is given in Table 2, where the parameter (p, p) is taken as a measure of the completeness of the basis sets employed. The ^{13}C shielding data are reported both for the gauge origin chosen at the centre of mass (cm) and at one of the carbon atoms in the molecule (c). It is clear that the results are both gauge- and basis-set-dependent. Since (p, p) indicates the number of electrons involved in the calculation, it is possible to perform a linear extrapolation of the calculated shielding results with respect to (p, p) . The limit of 360 is chosen, since this is the total number of electrons for C₆₀. In this way, the ^{13}C shielding values are obtained as 97.0 ppm when the gauge origin is taken to be at the centre of mass and 46.2 ppm for the choice of a carbon atom as gauge origin. The latter is clearly in better agreement with the experimental value of 43.0 ppm.¹⁵ The C₆₀ shielding results show rather graphically the necessity of using large basis sets to obtain reliable data from common origin calculations and the requirement of an appropriate choice of gauge origin.

3.2 Local Origin Calculations

An alternative to using large basis sets to overcome the gauge problem is to introduce gauge factors into either the atomic orbitals of the basis set or into the MOs of a CHF calculation. This procedure can lead to shielding results that are independent of gauge origin, even though the calculation is an approximate one. London¹⁶ proposed the inclusion of gauge factors in calculations by means of gauge-included atomic orbitals (GIAOs). The resulting complex orbitals ψ_n are used in place of the usual, real, atomic orbitals ϕ_n located at $\mathbf{R}_n$:

$$\psi_n = \phi_n \exp \left[-\frac{ie}{h} \mathbf{A}(\mathbf{R}_n) \cdot \mathbf{r} \right] \quad (13)$$

and the complex phase factor contains the vector potential $\mathbf{A}(\mathbf{R}_n)$ for the magnetic field evaluated at the point $\mathbf{R}_n$.

Ditchfield^{17–19} and others have used this approach in shielding calculations with some success. A development of the GIAO method, in conjunction with analytical derivative theory, has resulted in the production of some very interesting shielding results with modest basis sets.²⁰

In another development, exponential gauge factors have been introduced into the MOs employed in shielding calculations.^{21–24} This procedure employs individual gauge

Table 2 Comparison of Calculated and Experimental ^{13}C Shieldings (in ppm) for C₆₀ Obtained Using Various Basis Sets and Two Choices of Gauge Origin

Basis	(p, p)	$\sigma(\text{cm})$	$\sigma(\text{C})$
STO-3G	90.1	270.4	656.8
STO-3G*	186.4	211.0	447.0
6-31G	176.3	203.8	461.2
6-31G*	243.9	173.2	306.4
Extrapolation	360.0	97.0	46.2
Experiment		43.0	43.0

origins for different localized molecular orbitals (IGLO). In the IGLO calculations, the MOs used, ψ_k , are related to the usual MOs ϕ_k by

$$\phi_k = \exp(i\hat{\lambda}_k) \psi_k \quad (14)$$

where $\hat{\lambda}_k$ is a local multiplicative operator proportional to the applied magnetic field $\mathbf{B}$ and the ϕ_k are expanded in powers of $\mathbf{B}$. Both the GIAO and IGLO methods may be referred to as local origin variants of the CHF method, since the gauge origins in the calculations are attached to each nucleus in turn. In this way, the gauge problem is overcome. A further advantage of the IGLO procedure is that it furnishes a way of identifying shielding contributions that arise from specific electrons in the molecule. Consequently, shielding contributions can be attributed to electrons on the atom in question, on neighboring atoms, or involved in bonding between atoms. A comparable approach has been proposed in which different gauge origins are chosen for different pairs of orbitals, which may be either atomic or molecular orbitals.²⁵

An alternative to CHF calculations of second-order magnetic properties is the equations of motion (EOM) procedure.²⁶ The random phase approximation (RPA) is a well-known means of obtaining results from the EOM approach. Various methods for calculating nuclear shielding within the RPA have been considered. Some involve a common origin,^{27,28} whereas localized MOs with local origins (LORG) have also been employed.^{29,30} The LORG approach differs from the GIAO and IGLO methods in that complex orbitals are not explicitly introduced. Rather, angular momentum terms are expanded relative to a local origin for each orbital; by means of the RPA, shielding expressions are produced that are independent of gauge origin. The LORG method results in a localization of the molecular orbitals, which provides a pathway to the decomposition of the nuclear shielding into individual local bond and bond–bond contributions. Thus, the LORG and IGLO methods of calculating nuclear shieldings are analogous to each other.

In comparing the relative merits of the GIAO, IGLO, and LORG methods, it should be mentioned that the GIAO procedure appears to be the more efficient in terms of the convergence of the shielding value with respect to the size of basis set used,²⁰ whereas the IGLO and LORG calculations furnish shielding contributions that may be attributed to specific molecular regions. Such results are germane to many chemically oriented discussions, and thus have a fairly general appeal. Since the GIAO, IGLO, and LORG calculations can all be performed with different levels of basis set quality, the results are found to be dependent upon the choice of basis sets used. In Table 3, the results of some shielding calculations

Table 3 Comparison of Some ^{13}C Shieldings and Their Anisotropies (in ppm) Produced by IGLO, LORG, and GIAO Calculations, and by Experiment

Molecule	IGLO	LORG	GIAO	Experimental

		60.5	77.3	63.0
H_2CO	-3.8	4.0	2.6	-8.0
	183.8	183.0	196.5	

by these three methods are compared. The results given are obtained by the use of medium sized basis sets; for example, sets of triple zeta quality with a set of d polarization functions for the heavy atoms. In comparison with the experimental results, the calculated data are in reasonable agreement. The success of these local origin methods in nuclear shielding calculations appears to reside in the omission of large terms of opposite sign, which would have canceled exactly in the limit of a complete basis set. This is analogous to the cancellation of the gauge-dependent terms in the Ramsey formulation, equations (8)–(12). Consequently, for an incomplete basis set calculation, the local origins provide a damping of basis set errors in long-range shielding contributions.³¹

An example of the dependence of GIAO-calculated ^{13}C shieldings on the choice of geometry and basis set is provided in Table 4.³² The use of experimental geometries is indicated by NOOPT; also included are optimized geometries from ab initio calculations using 4-31G and 4-31G** basis sets. The ^{13}C shieldings are calculated with 3-21G, 4-31G, and 4-31G** basis sets. The best agreement with the experimental shieldings is provided by the calculations using experimental geometries and the 4-31G** basis set; in this case, the average least-squares error for the set of molecules studied is 2.7 ppm.

Another method of tackling the gauge problem in nuclear shielding calculations is to use individual gauges for atoms in molecules (IGAIM).³³ The IGAIM method produces the induced current density distribution of a molecule from its constituent atoms; it differs from the GIAO, IGLO, and LORG procedures in that the gauge origins in IGAIM are determined by properties of the charge density in real space rather than by the behavior of the chosen basis functions in the Hilbert space of the molecular wavefunction.

The atom in a molecule model consists of a partitioning of the real space of a molecule into atomic basins.³⁴ Using this procedure, the shielding tensor is presented as a sum of separate contributions from each atom in a molecule. Consequently, IGAIM shielding calculations result from a sum of atomic contributions that are produced by taking each nucleus in turn as a gauge origin. Each of these atomic calculations employs a small basis set, thus giving a time advantage over the GIAO, IGLO, and LORG methods, which require larger, molecular, basis sets. In contrast to this, the GIAO, IGLO, and LORG methods provide the shieldings of

all of the nuclei in a given molecule from one calculation, whereas the IGAIM method requires many calculations if all the shieldings are required. Thus, the time required for IGAIM calculations on larger molecules, with many nuclei of interest, can become prohibitive.

The results of some ^{13}C IGAIM shielding calculations are given in Table 5, where they are compared with the results obtained from conventional CHF calculations using the same basis set. In the latter case, the common gauge origin is placed at the nucleus whose shielding is being computed. As shown in Table 5, the IGAIM results are in much better agreement with experiment than those given by the CHF calculations.

3.3 Calculations on Larger Molecules

In general, satisfactory nuclear shielding results can be obtained from calculations on fairly small molecules containing relatively light atoms. An exception should be mentioned—namely, those cases where electron correlation effects are important. As we shall see later, these can usually be accounted for by calculations extending beyond the CHF limit.

A potential barrier to calculations on larger molecules is the requirement of a relatively large basis set in order to obtain shielding results that are convergent with respect to choice of basis set. One way of dealing with this problem is to use a relatively large, locally dense, set of functions for the atoms containing the nuclei of interest. The other atoms in the molecule are then provided with considerably smaller sets of functions. It has been demonstrated that the calculated nuclear shieldings obtained using locally dense basis sets are in good agreement with those provided by calculations with balanced basis sets, and there is also a significant saving of cpu time.³⁵

For atoms from the first long row of the Periodic Table, it is suggested that a suitable locally dense basis set is 6-311G(d, p). This can be successfully coupled with a 3-21G set for the remaining atoms in the molecule. A number of GIAO calculations have used this technique with success, including those for the amide group in glycylglycine,³⁶ for the $-\text{CH}=\text{N}-$ group of benzyldineaniline³⁷ and for the proton shielding anisotropy of $(\text{H}_2\text{O})_{17}$ as a model for ice.³⁸

In deciding whether a locally dense basis set is an appropriate choice, some consideration has to be given to the bonding situations of the atoms in question. In general, carbon and phosphorus may be taken as singly dense species, whereas hydrogen, oxygen, and nitrogen are best treated as part of a locally dense pair of atoms, the other member being the atom that is directly bonded.

Other approaches to calculating the shieldings of large molecules include ‘direct’ methods³⁹ and a method for partitioning the shielding into a number of contributions.⁴⁰ ‘Direct’ techniques reduce the storage requirements for two-electron integrals by calculating the integrals each time they are required, rather than storing them. This approach has been developed in conjunction with IGLO calculations, and is termed DIGLO. It has been applied to molecules with about 1000 basis functions.⁴¹ Since the number of two-electron integrals to be calculated is proportional to the fourth power of the number of electrons included in a molecular calculation, it is clear that ‘direct’ methods are of great relevance to considerations of shielding calculations on larger molecules. A proposal to partition the shielding contributions into short-range, long-range, and others has been put forward in conjunction with

3.4 Effects of Geometry on Nuclear Shielding

Normally, solution state NMR measurements are taken at around 300 K. The molecules in gaseous and liquid samples are usually mobile at such temperatures, and collisions occur, providing the opportunity for molecules to populate excited vibrational and rotational states on the NMR timescale. As noted previously, nuclear shielding calculations are usually performed by assuming a rigid nuclear framework, and usually the equilibrium configuration is taken as the structure on which the calculations are based. Consequently some account of rotational-vibrational effects may be necessary in comparing experimental and calculated nuclear shielding data.⁴²

As the accuracy of nuclear shielding calculations increases, the significance of including rotational-vibrational corrections in a comparison of theoretical and experimental results becomes more apparent. It has been reported that the rotational-vibrational effects on ^{19}F shieldings can be as large as -9.5 to -18.0 ppm for some haloethanes at 300 K⁴³ and from -6.8 to -16.4 ppm for some halomethanes.⁴⁴ These data show the difficulty that can arise in choosing a suitable geometry upon which to base shielding calculations when there is a strong geometrical dependence of shielding. In many cases, accurate experimental geometries are unknown, and minimized HF geometries are chosen for shielding calculations.

Some calculated first derivatives of the shielding of some ^{13}C , ^{15}N , ^{17}O , and ^{19}F nuclei in a variety of small molecules

Table 6 Some First Derivatives of IGLO-Calculated Nuclear Shieldings with Respect to Bond Length r_{AX} and Bond Angle α_{XAX} for ^{15}N , ^{29}Si , and ^{31}P

SiF_4	80	
P_2	−2055	
PH_3	−464	−332
PF_3	−243	−54

have been reported.⁴⁵ The derivatives have negative values, showing that the shielding is expected to decrease as the bond length increases. This is in agreement with the available experimental data.⁴² In addition, the observed shielding derivatives become more negative as the magnitude of the nuclear shielding decreases, as is found to be the case experimentally.⁴²

Table 6 shows the results of IGLO calculations of some first derivatives of some ^{15}N , ^{29}Si , and ^{31}P shieldings as a function of bond length and bond angle.⁴⁶ The dominant contribution to the change of shielding as the bond length varies arises from the paramagnetic shielding term. An increase in bond length produces a decrease in the relevant electronic excitation energies, which furnishes an enhanced paramagnetic contribution to the shielding tensor. Regrettably, a direct comparison between the results given in Table 6 and experiment is not possible, because the appropriate experimental data appear to include assumptions that may not be valid.⁴⁶

In addition to rotational–vibrational effects, there are specific and nonspecific intermolecular interactions that may influence nuclear shielding. These medium effects result from interactions of a given molecule with its environment, thus influencing the electronic structure for a given nuclear configuration, as well as modifying the molecular geometry. Specific interactions, such as hydrogen bonding, may be treated theoretically using the supermolecule approach. Nonspecific interactions can be included by means of Onsager's reaction field treatment of polar molecules.⁴⁷ A derivative of this approach is the self-consistent reaction field model (SCRF).⁴⁸

Both solution and solid state experimental NMR shieldings may contain a component due to medium effects. However, these contributions are usually ignored in nuclear shielding calculations at the ab initio level. The SCRF model has been applied to a study of aminoborane.⁴⁹ The report deals mainly with the influence of the reaction field on the geometry of aminoborane. IGLO calculations are performed to give the ^{11}B shielding relevant to the geometry produced by the reaction field effects. Unfortunately, the shielding calculations do not appear to have been performed in the presence of the reaction field, and so any influence of this field on the electronic structure of aminoborane has not been included.

Nuclear shielding calculations in the presence of a reaction field are well established in the area of semiempirical calculations. No doubt, they will become part of the ab initio shielding calculation scene in due course.

Table 7 Comparison of Some ^{95}Mo Chemical Shifts (in ppm from $[\text{MoO}_4]^{2-}$) as Obtained by Various Calculations and Experiment

3.5 Calculations of Heavy Metal Shieldings

Ab initio calculations using a common origin and modest basis sets, within finite perturbation theory (FPT), have been performed for the metal shieldings of a number of compounds containing Cu, Zn, Ag, Cd, and Mo.^{50–54} In general, the results presented appear to reproduce satisfactorily a number of the experimental trends. However, it seems probable that some of the agreement with experiment may be somewhat fortuitous, since such shieldings are expected to be quite solvent-dependent, the solution geometries of the compounds studied are not well known, and possible electron correlation and relativistic effects are absent from the calculations. To date, there are no ab initio shielding calculations on heavy metals that include electron correlation and relativistic effects. However, it is reasonable to assume that they are not insignificant. A further aspect of heavy metal shielding calculations that requires consideration is the difficulty of comparing them with experimental results. In general, there are no absolute shielding scales available for heavy metals at the present time. Consequently, comparisons of theoretical and experimental data can only be performed for shielding differences, i.e., chemical shifts between two species.

Molybdenum shielding calculations by the LORG^{55,56} and the, less accurate, sum over states (SOS) perturbation methods⁵⁷ have also been reported. Some of these results are presented as chemical shifts with respect to $[\text{MoO}_4]^{2-}$ in Table 7, where they are compared with the results produced by the FPT method⁵² and with experiment.^{58–60} In the LORG calculations, the best sets used are of triple zeta quality for the metal d orbitals and 4-31G* for the ligand atoms. Thus, the LORG results are expected to be the most accurate and reliable of those given in Table 7. However, they do not appear to be in the best agreement with the available experimental data. Analysis of the LORG shielding results for molybdenum reveals that the ^{95}Mo shielding is not dominated by contributions arising from the metal orbitals. This contrasts with the reports based upon FPT calculations.^{49,50} Perhaps this difference is not too surprising, since the FPT method uses a common origin and a modest basis set, which is expected to result in a poor description of ligand electron contributions to the shielding of the metal. FPT common origin calculations have also been reported for the ^{93}Nb shieldings of nineteen niobium hexahalide mixed complexes.⁶¹ The calculations predict a shielding range of 2300 ppm in passing from NbF_6^{3-} to NbBr_6^{3-} , which mirrors the observed chemical shift range.

Other heavy metal ab initio shielding calculations include those on titanium,^{62,63} tin, cadmium-53,⁶⁴ and zinc.^{65,66} In general, these calculations show satisfactory agreement with experimental data. A summary of the current situation

regarding heavy metal nuclear shielding calculations must include reminders that absolute shielding scales for these nuclei are unavailable, that the solution geometries of the species considered are often unknown, and that rather more extensive basis sets appear to be required. Significant advances in these calculations would be made if the basis sets used were optimized such that the shielding calculations were convergent with respect to basis set. In addition, some attempt should be made to estimate the importance of relativistic and electron correlation effects on the results of these nuclear shielding calculations.

3.6 Electron Correlation Effects

In recent years, it has become possible to perform CHF nuclear shielding calculations, using either common or local origins, that are sufficiently close to the HF limit that some imperfections of HF theory are apparent from a comparison of the calculated and experimental shieldings. Predictably, the absence of electron correlation effects in HF calculations shows most noticeably in ‘electron-rich’ cases, for example, when lone pair electrons are present—especially when multiple bonding occurs simultaneously. Such cases give rise to nearly degenerate and low lying electronic excited states, which are not well described by the single determinant HF MO eigenfunctions. An early attempt to move beyond the HF limit in nuclear shielding calculations was the sum-over-states procedure with configuration interaction (CI).⁶⁷ This common origin method was applied to some first and second row hydrides, and the results obtained are in satisfactory agreement with experiment. It should be noted that the molecules studied in this work are ones for which electron correlation effects are not expected to be large. More recently, the local origin methods for calculating nuclear shieldings have been enhanced by the addition of techniques for including electron correlation effects. The GIAO method has been extended by means of many body perturbation theory (MBPT).^{68,69} Similarly, a nonperturbative multiconfiguration extension of the IGLO procedure has been reported.⁷⁰ This is referred to as MC-IGLO. Finally, the LORG method of calculating nuclear shieldings has been combined with the second-order polarization propagator (SOPPA) technique⁷¹ to produce the second-order LORG or SOLO procedure.⁷² Table 8 shows the results of some GIAO-MBPT calculations for ¹⁷O shieldings.⁶⁸ The effect of including electron correlation is to increase the calculated values of the ¹⁷O shieldings, usually bringing them into closer agreement with experiment.

Table 8 Comparison of Some ¹⁷O Shieldings (in ppm) Produced by GIAO and GIAO-MBPT Calculations, and Experiment

Molecule	GIAO	GIAO-MBPT	Experimental
H ₂ O	323.18	339.79	357
H ₂ O ₂	139.01	150.88	134
CO	−113.47	−54.06	−40.1 ± 17.2
H ₂ CO	−471.40	−345.02	−312.1
CH ₃ OH	341.55	354.41	344.9
CO ₂	200.37	236.37	243.4
OF ₂	−471.13	−465.53	−473.1
NNO	107.54	192.12	200.5

Table 9 Comparison of Some ¹H, ¹³C, ¹⁷O, and ³¹P Shieldings (in ppm) Produced by SCF-IGLO and MC-IGLO Calculations, and Experiment

Molecule	Nucleus	SCF-IGLO	MC-IGLO	Experimental

Pyridazine	−240	−235	−197	−156
1,2,4-Triazine				
N-3		−76	−42	−54
N-2		−171	−151	−134
N-1		−255	−207	−178

A comparable finding is given in Table 9 for some MC-IGLO calculations of ¹H, ¹³C, ¹⁷O, and ³¹P shieldings.⁷³ Not surprisingly, the electron correlation effects on the nuclear shieldings are small for methane and phosphine, but much more significant for fluorine, carbon monoxide, and ozone, which are ‘electron-rich’ molecules. For the central oxygen of ozone, the effect of including electron correlation in the calculation is to increase the predicted shielding by over 2000 ppm. As in the case of the GIAO-MBPT calculations, the MC-IGLO results show an increase in shielding over that given by the corresponding IGLO calculations. The exception is the fluorine molecule. The results of some LORG and SOLO nitrogen shielding calculations are compared in Table 10.⁷⁴ The conjugated heterocycles chosen for the study represent cases where electron correlation effects are expected to be important. As can be seen, the inclusion of electron correlation leads to an increase in the calculated nitrogen shieldings and usually to an improved agreement with experimental results. This is consistent with the view that taking account of electron correlation interactions results in an improved description of the molecular electronic excited states, so that the energies of the lower lying members of the excited states are increased; this results in a smaller paramagnetic contribution to the nuclear shielding, so that the total shielding increases.

A comparison of the LORG and SOLO data given in Table 10 with experiment shows root mean square errors of 49.2 and 19.9 ppm respectively. Thus, the case is strongly made for the necessity of including electron correlation effects in nuclear shielding calculations on ‘electron-rich’ molecules. As a caveat, it should be mentioned that the amount of influence of electron correlation on the calculated shieldings

Table 11 Comparison of Some ^{15}C , ^{15}N , ^{17}O , ^{19}F and ^{31}P Shieldings (in ppm) Produced by GIAO and CDFT Calculations, and Experiment

Molecule	Nucleus	GIAO	CDFT	Experimental

F_2	F	-181.4	-197.8	-193.8

depends upon the method chosen, as well as on the basis set and geometry.

Density functional theory (DFT) is an alternative to HF methods for describing molecular electronic structure.^{75,76} A particularly appealing aspect of DFT is that electron correlation effects are explicitly included in the calculations. Coupled DFT (CDFT), together with the IGLO method, has been used in some nuclear shielding calculations for molecules where electron correlation effects are anticipated to make a significant contribution to the calculated shieldings.⁷⁷ In Table 11 the CDFT shielding results are compared with experiment and with the results of some GIAO calculations in which electron correlation effects are not included.^{78,79} It is noteworthy that the CDFT results are in much better agreement with experiment than are the uncorrelated GIAO data. This serves again to stress the importance of electron correlation effects on the observed shieldings of nuclei in 'electron-rich' molecules. However, it should also be noted that the electron correlation methods of calculating nuclear shieldings used to date tend to overemphasize the importance of correlation effects; this shortcoming can be overcome by using more sophisticated electron correlation methods such as multiconfiguration SCF with coupled clusters (MCSCF-CC) and the MP₄ theory, for example.

4 SEMIEMPIRICAL MOLECULAR ORBITAL CALCULATIONS

During the last few years, ab initio calculations of nuclear shieldings have become increasingly popular for smaller molecular systems, mainly because of the widespread availability of enhanced computer power. Prior to that, semiempirical calculations were generally popular and widely accepted. Such calculations have a good record for indicating shielding trends in series of closely related molecules, although they are often unsuitable for predictive purposes—especially for comparison of the nuclear shieldings of molecules whose chemical properties are not closely related. There are still areas where ab initio shielding calculations have not yet been successfully applied, for example, for an extended network of atoms, and for investigating medium effects on nuclear shielding and relativistic effects on the shielding of heavier nuclei.

Pople's GIAO model provides the basis for the more successful semiempirical shielding calculations.^{80–83} In cases where only valence s and p electrons need to be considered for an atom A, the expressions for the rotationally averaged values of the local diamagnetic, σ_A^d , and paramagnetic, σ_A^p , terms are

$$\sigma_A^d = \frac{\mu_0 e^2}{12\pi m} \sum_{\mu}^A \rho_{\mu\mu} \langle \mu | r_{A\mu}^{-1} | \mu \rangle \quad (15)$$

$$\begin{aligned} \sigma_A^p = & -\frac{\mu_0 e^2 \hbar^2}{6\pi m} \langle r^{-3} \rangle_{r_p} \sum_j^{\text{occ}} \sum_k^{\text{unocc}} \frac{1}{E_k - E_j} \\ & \times \left[(C_{yAj} C_{zAk} - C_{zAj} C_{yAk}) \sum_B (C_{yBj} C_{zBk} - C_{zBj} C_{yBk}) \right. \\ & + (C_{zAj} C_{xAk} - C_{xAj} C_{zAk}) \sum_B (C_{xBj} C_{yBk} - C_{yBj} C_{xBk}) \\ & \left. + (C_{xAj} C_{yAk} - C_{yAj} C_{xAk}) \sum_B (C_{xBj} C_{zBk} - C_{zBj} C_{xBk}) \right] \quad (16) \end{aligned}$$

where $\rho_{\mu\mu}$ is the charge density in the atomic orbital μ , which is at an average distance of $r_{A\mu}$ from nucleus A, and C_{xAj} is the LCAO coefficient of the p_x orbital on atom A in the molecular orbital j , and so on. The summation over the atoms B includes A; consequently, σ_A^p is zero unless both A and B possess valence p electrons. E_k and E_j are the energies of the unoccupied and occupied molecular orbitals k and j , respectively; the excitation energies $E_k - E_j$ are those of the excited singlet states, which are mixed with the ground state by the magnetic field used in the NMR experiment. From these comments, it may be apparent that semiempirical nuclear shielding calculations can provide the basis for an approximate understanding of chemical shifts in terms of molecular electronic structure. In general, the absolute shielding values produced by these calculations are not too reliable, but changes in nuclear shielding as a function of molecular structure can be predicted to a reasonable accuracy by semiempirical methods. More extensive accounts of semiempirical nuclear shielding calculations are to be found in the literature.^{84–86} Various semiempirical parameter schemes have been used to calculate nuclear shieldings. Generally, reasonable agreement with experiment has been obtained for ^{13}C , ^{14}N , ^{17}O , and ^{19}F shieldings with CNDO/S and INDO/S parameter schemes (CNDO/S = complete neglect of differential overlap for spectroscopy; INDO/S = intermediate neglect of differential overlap for spectroscopy). In these calculations, almost the full range of observed chemical shifts for a given type of nucleus is attributed to changes in the local paramagnetic term, and this may be discussed in the terminology of charge densities, bond orders and excitation energies as shown by equation (16). For calculations of the shieldings of carbon and nitrogen nuclei, the INDO/S scheme is found to give results that are in closest agreement with experiment.^{87,88}

4.1 Nuclear Shielding of Macromolecules

In polymers, electrons are usually not constrained to well-defined regions of a molecule, in contrast to the situation normally found in small molecules. Consequently, molecular orbital calculations on monomeric species are not readily transferable to polymers because of differences in electronic

structure. In calculations on polymers, additional approximations are required; for example, the tight binding (TB) approximation⁸⁹ has been successfully used in semiempirical calculations of the nuclear shieldings of nuclei in infinite chains.⁹⁰ In general, the best choice of parameter scheme for these calculations is found to be the INDO/S set.⁹¹ An example is provided by the case of *cis*- and *trans*-polyacetylenes, where the ¹³C shieldings are satisfactorily reproduced by the TB-INDO/S shielding calculations.⁹¹

4.2 Medium Effects on Nuclear Shielding

Solute and solvent molecules may interact in both specific and nonspecific ways, both of which may influence the nuclear shielding. Specific interactions include hydrogen bonding, protonation, and complex formation, which have been included in many *ab initio* and semiempirical nuclear shielding calculations.

Nonspecific shielding influences can be produced by bulk susceptibility effects, van der Waals effects, neighbor susceptibility anisotropies, and electric field effects. The modus operandi of these effects is by means of electronic interactions between the dipole moments of the solute and solvent molecules.⁹² The solvaton model⁹³ has been used together with semiempirical molecular orbital calculations to estimate the effects of nonspecific solute–solvent interactions on nuclear shielding in a number of cases. In general, the results obtained from calculations using the solvaton model within the INDO/S–SOS framework are both qualitatively and quantitatively reliable.⁹⁴ The presence of the lone electron pair renders nitrogen nuclear shieldings particularly susceptible to solute–solvent interactions. The greatest influence of this kind for neutral species has been reported in a study of some azine heteroaromatics;⁹⁵ pyridazine shows a range of about 50 ppm for its solvent-dependent nitrogen shielding. Solvaton-based nuclear shielding calculations show that about half of this range is produced by nonspecific solute–solvent interactions.

4.3 Relativistic Effects for Heavy Nuclei

There are two relativistic effects that should be considered in discussions of the shielding of heavy nuclei.

A relativistic electronic mass increase causes the radii of the innermost orbitals to contract. This contraction may lead to enhanced screening of the nuclear charge as far as the outer electrons are concerned; thus the radii of their orbitals may increase. Equations (15) and (16) show that any change in the separation between a given nucleus and its surrounding electrons is expected to result in marked changes in both the diamagnetic and paramagnetic shielding contributions.

The second relativistic effect to be considered is that arising from the breakdown of Russell–Saunders coupling in favour of *j–j* coupling of electronic angular momenta. As a consequence of this breakdown, some spin triplet character can be introduced into the singlet ground state of a diamagnetic molecule. Resulting from this, a local magnetic field is produced at the nucleus, which produces a change in nuclear shielding.

The Dirac model has been employed to produce a relativistic analog of Ramsey's theory of nuclear shielding.^{96–100} To date, only semiempirical molecular orbital calculations of

relativistic contributions to the nuclear shielding of heavy atoms have appeared.¹⁰¹ The results show that relativistic effects are significant for the proton shieldings of the hydrogen halides, with the major influence arising from the spin–orbit coupling-induced changes in the wavefunctions. In another study, a comparison of CHF and relativistic semiempirically calculated shieldings for the series CX and CX₂, where X = O, S, and Se, shows some expected relativistic contributions to the paramagnetic shielding terms of the heavier nuclei.¹⁰²

It is to be anticipated that the areas outlined here, as still being part of the purview of semiempirical calculations of nuclear shieldings, will become part of the remit of *ab initio* calculations in the not too distant future. In order to examine more thoroughly the results of more accurate shielding calculations, there are some experimental demands to be met. More careful measurements of solvent effects on nuclear shieldings are required; absolute shielding scales need to be established for more nuclei; and there is a requirement for more gas phase data to permit accurate comparisons of calculated and experimental data. In addition, it should not be forgotten that the effects of rotational–vibrational averaging should be included in experimental results. Such improved measurements are required for most NMR nuclei; they are probably more readily obtained for the lighter nuclei, and it could be several years before a reliable experimental basis is available for a more coruscating investigation of the results of *ab initio* shielding calculations on heavier nuclei.

1 INTRODUCTION

In the last 10 years, our ability to calculate chemical shielding tensors has increased greatly. The advances have originated in new theoretical developments to mitigate the gauge origin problem, advances in the algorithms used in the quantum mechanical computer programs, and great improvements in computer hardware performance. In recent years, the improvements of experimental methods to measure the principal values and the full chemical shift tensors (see also *Chemical Exchange Effects on Spectra*, *Chemical Shift Tensors*, and *Chemical Shift Tensors in Single Crystals*) have produced a large collection of experimental values of the principal components of the chemical shift tensors and some information on the full tensors,¹ giving further impetus to the development of better methods for calculating chemical shifts. It is significant to realize that when comparing experimental and calculated values of chemical shifts it is important to compare the full tensors, or at least the principal values, because it is well-documented in the literature² that in certain cases the agreement between experimental and calculated isotropic shift may arise from a fortuitous cancellation of errors in the calculated principal components.

Several modern methods for calculating chemical shieldings are described in detail elsewhere in this Encyclopedia (see Related Articles). All these methods can produce fairly accurate results and with the current computational technology

calculations involving several hundreds of basis functions in molecules with 20–30 nonhydrogen atoms have become common.

In this article important examples of the use of calculations of chemical shielding tensors as an aid in solving chemical/structural problems are presented. In the examples the importance of calculating the full chemical shielding tensors over the use of the isotropic values is emphasized. The article does not attempt to present a comprehensive description of all the chemical problems that have been or can potentially be addressed using calculations of chemical shieldings; the article is limited to a brief description of some of the most interesting problems which, in the author's opinion, have benefited from this type of calculation. The selection has been somewhat arbitrary and perhaps biased by the author's own research interests. Apologies are made for the omission of many other important pieces of research that have not been included in this article. It is hoped that the material presented here will give the reader a flavor of how to use chemical shift tensor calculations in molecular sciences. For those interested in a comprehensive survey of the applications, reference should be made to the annual accounts on the field published by Jameson.³ The examples used in this article to illustrate the importance of calculating the chemical shielding tensors are listed in the Table of Contents.

2 THE USE OF CALCULATIONS OF CHEMICAL SHIELDING TENSORS FOR THE ASSIGNMENT OF THE ORIENTATIONS OF THE PRINCIPAL VALUES OBTAINED FROM DISORDERED SAMPLES

The assignment of the principal values of the tensor into the molecular frame is a critical step in obtaining information on the relationship between electronic structure and chemical shielding. Several reasonably simple experimental methods have been developed to measure the principal values of the chemical shielding tensors in disordered solids,¹ but, unfortunately, only the principal values from the tensor are available from these experiments; much more complex ones, involving dipolar coupling, are necessary to obtain the orientation of the principal axes of the tensor. Even in cases of high molecular symmetry, in which the orientations of the principal axes are known by symmetry, it is necessary to use theoretical arguments to decide which principal value corresponds to each principal direction. The only exception to this rule can be found in molecules with a C_3 axis or one of higher symmetry, in which case there are only two principal components of the shielding tensor, one lying along the symmetry axis and the other perpendicular to the axis with a degeneracy factor of two.

A classical example of this problem is the assignment of the principal components of the $^{13}\text{CH}_2$ chemical shift tensors in cyclic alkanes.⁴ In Table 1 the measured principal values of the tensors in cyclopropane, cyclobutane, and cyclopentane are presented by rank order. From the table we can conclude that the calculations, which have been undertaken using a modest double zeta basis, reproduce the measured principal values quite well, but a simple inspection of this table also indicates that all the principal components are quite sensitive to the size of the alkane ring and to the CCC angle. This

2 SHIELDING TENSOR CALCULATIONS

Table 1 ^{13}C Chemical Shift Principal Values in Cyclopropane, Cyclobutane, and Cyclopentane Presented by Rank Order. The Experimental Values are Referenced to External Liquid TMS and the Calculated Values to the Calculated Value of TMS using a Double Zeta Basis⁴

		Cyclopropane	Cyclobutane	Cyclopentane
δ_{11}	experimental value	22	39	49
	IGLO	38	35	49
δ_{22}	experimental value	2	23	21
	IGLO	6	27	31
δ_{33}	experimental value	-36	14	12
	IGLO	-39	9	16

is quite contrary to the actual physical situation depicted in Figure 1, where the experimental principal components have been ordered according to their spatial orientation obtained from the calculations. Figure 1 shows that only the component perpendicular to the CCC plane, δ_{CC} , is highly dependent on the CCC angle. The other two components show only a very modest dependence on the size of the alkane ring. Only theoretical calculation of the chemical shielding tensors can provide the information required to make use of the

Figure 1 ^{13}C shift principal components are shown as a function of the CCC angle in cyclopropane, cyclobutane, and cyclopentane. The orientation of the principal axes obtained from theoretical calculations of the chemical shielding tensors is as follows: δ_{AA} : lies in the HCH plane bisecting the HCH angle; δ_{CC} : lies perpendicular to the HCH plane; and δ_{BB} : lies perpendicular to the CCC plane. (Reproduced by permission of The American Chemical Society from J. C. Facelli, D. M. Grant, and J. Michl, *Acc. Chem. Res.*, 1987, **20**, 152)

experimental measurements in a consistent way. Note that the calculations of the chemical shieldings produce the complete tensor in the molecular frame, therefore complete information on the orientation of the principal axis of the shielding is available from the calculations. The agreement between the calculated and the experimental values gives confidence in using spatial assignments based on the orientations of the calculated principal values.

3 THE USE OF CHEMICAL SHIELDING TENSOR CALCULATIONS FOR THE ASSIGNMENT OF ^{13}C RESONANCES IN THE SOLID PHASE

The assignment of resonance frequencies to individual nuclei has always been a significant problem in NMR spectroscopy. Over the years a number of techniques have been developed to make the spectroscopic assignments more reliable in complex molecules. The most common assignment techniques used in modern liquid NMR are based on the additivity effects of the electronic substituent, measurements of coupling constants, backbone connectivities derived from INADEQUATE experiments, and multidimensional experiments correlating chemical shifts and coupling constants of directly bonded nuclei. Unfortunately, these methods are not readily applicable to solid state measurements due to relaxation, sensitivity, and linewidth problems. The most common tool for the assignment of carbon resonances in the solid state is a comparison of the chemical shift values with their liquid shift values. This method is only adequate for assigning resonances separated by several ppm, otherwise the differential shifts observed in going from the liquid to the solid phase are of the same magnitude as the differences between the resonance frequencies of the nuclei and the assignments become unreliable. A classical example of this problem is the assignment of the ^{13}C resonances of crystalline glucose which required the use of selective isotopic enrichment.⁵

In principle, calculations of isotropic chemical shifts can be used for chemical shift assignments, but they also become unreliable when the isotropic shifts differ by less than 2–3 ppm, which is the limit of reliability of our current theoretical methods. The use of the principal tensor components, which magnify the dispersion of the chemical shifts, partially overcomes the problem when at least one of the principal values of the shift tensors in question differs by more than 4–5 ppm, thus making assignments from theoretical calculations reliable. For instance, the ^{13}C chemical shifts of the phenyl carbons directly bonded to the oxygen in solid *p*-tolyl ether, have principal components of $\delta_{11} = 238.3$ ppm, $\delta_{22} = 147.4$ ppm, $\delta_{33} = 74.4$ ppm, and $\delta_{11} = 238.6$ ppm, $\delta_{22} = 160.7$ ppm, $\delta_{33} = 74.4$ ppm, respectively.⁶ The isotropic values of 153.3 ppm and 157.9 ppm are too close to make any reliable assignment based on the calculated values, and the liquid values are of no use in this case because the two carbons are equivalent in solution with an isotropic chemical shift of 155.2 ppm. The X-ray structure of this compound shows that the two phenyl moieties form a dihedral angle, α [shown for diphenyl ether (**1**) in Scheme 1], of approximately 90°. Using the X-ray geometry of the compound, the calculated chemical shifts tensors show a large difference of 11.8 ppm between the δ_{22} components of the carbons in question. This

Scheme 1. Structure of diphenyl ether. The X-ray studies predict a dihedral angle of approximately 10° between the two phenyl moieties.

allows a reliable assignment of these carbons which would not be possible without the calculation and measurement of the principal values. The carbon with the largest δ_{22} component, 160.7 ppm, corresponds to an aryl carbon of the ring for which the C- ^{13}C -O-Ph moiety is almost planar. The carbon with the smaller δ_{22} component, 147.4 ppm, corresponds to the aromatic ring for which the dihedral angle C- ^{13}C -O-Ph is close to 90° . This larger shift in δ_{22} can be rationalized with the smaller C_{aryl}-O bond order for an out-of-plane configuration compared with the bond order for the planar configuration.

Even when full tensor data are available, calculations of chemical shift tensors can be important in the assignment of the individual carbon resonances and their orientation in the molecular frame when the combined symmetry requirements of the NMR experiments and the crystalline structure lead to ambiguous assignment of the resonances. An example of this problem was described in the analysis of the ^{13}C chemical shift tensors of pyrene.⁷

4 STUDIES OF THE ADDITIVITY OF ELECTRONIC SUBSTITUENT EFFECTS IN THE TENSOR COMPONENTS OF CHEMICAL SHIFT TENSORS

The additivity of the electronic substituent effects has been one of the most powerful tools for the assignment and rationalization of ^{13}C chemical shifts,⁸ but most of the work in this area has concentrated on the isotropic shift values. This type of analysis for the full chemical shift tensors and/or their principal values has been very limited, partially due to the absence of precise data on the substituent effects on the tensor values. Note that this type of analysis requires a knowledge of the shift values with an accuracy of <1 ppm in several derivatives of the parent compound. The most comprehensive study of the electronic substituent effects on ^{13}C chemical shift tensors of aromatic carbons has been presented by Carter et al.⁹ who analyzed the electronic substituent effect of the methoxy group in polysubstituted methoxybenzenes. The data used in the analysis were derived from single crystal studies.

For conformationally flexible substituents, like the methoxy group, the substituent effects in the liquid or solution phase represent only the thermal average of the substituent effects for different conformations. Frequently in the solid state the substituent is trapped in a fixed conformation and additional substituent parameters are necessary to describe the steric effect. For the methoxy group it is necessary to introduce a steric *ortho* effect to describe the differential substituent effect on the two carbons *ortho* to the substituent.^{10,11} Table 2 presents the substituent effect parameters for the methoxy group in substituted benzenes. The steric effect corresponds to the additional shift observed by the *ortho*

Table 2 Electronic Substituent Effect of the Methoxy Group on the ^{13}C Chemical Shift Principal Values in Polysubstituted Methoxybenzenes^a

	δ_{11}	δ_{22}	δ_{33}
<i>ipso</i>	11.3	30.0	58.3
<i>ortho</i>	-31.6	-7.7	8.1
steric ^b	-4.5	-1.9	-11.4
<i>meta</i>	-0.2	0.0	-4.4
<i>para</i>	-9.6	-14.3	-4.2

^aAll values in ppm from Carter et al.⁹. The TMS scale has been used in this table, i.e. a positive substituent effect means a deshielding of the carbon nucleus.

^bThe steric effect corresponds to the additional shift observed in the *ortho* carbon *cis* to the O-CH₃ bond.

carbon *cis* to the O-CH₃ bond. The values entered in Table 2 follow the trends commonly known from the rules of substituent effects, but it is noteworthy to observe the large anisotropies present in the substituent effects which in some cases are as large as 40 ppm.

Using chemical shift data from related compounds, we can use the information available from Table 2 to assign NMR resonances and to obtain conformational information. For example, the principal values of the chemical shift tensors for C-1 and C-3 in 2-methoxynaphthalene (**2**) (see Scheme 2) are $\delta_{11} = 176.7$ ppm, $\delta_{22} = 120.9$ ppm, $\delta_{33} = 18.1$ ppm, and $\delta_{11} = 198.7$ ppm, $\delta_{22} = 125.2$ ppm, $\delta_{33} = 24.4$ ppm, respectively. The conformation of the methoxy group in this compound is not known from diffraction techniques, but certainly the two energetically most favorably conformations, depicted in Scheme 2, are (**2a**) and (**2b**). Using the substituent parameters from Table 2, we can estimate the principal values of the shift tensors of C-1 and C-3 for the two conformations; we obtain for **2a**: (C-1: $\delta_{11} = 187.6$ ppm, $\delta_{22} = 130.7$ ppm, $\delta_{33} = 19.5$ ppm; C-3: $\delta_{11} = 196.0$ ppm, $\delta_{22} = 130.5$ ppm, $\delta_{33} = 18.5$ ppm) and for **2b**: (C-1: $\delta_{11} = 193.6$ ppm, $\delta_{22} = 132.6$ ppm, $\delta_{33} = 30.9$ ppm; C-3: $\delta_{11} = 192.0$ ppm, $\delta_{22} = 128.6$ ppm, $\delta_{33} = 7.1$ ppm). From these data one may immediately conclude that conformation **2a** is the most stable in the solid. Note that this conclusion is also supported by ab initio calculations and by reactivity considerations. While the additivity of the substituent effects in this case does not work perfectly, the amplification of the differences observed in the individual shielding components makes it possible to establish the preferred conformation of 2-methoxynaphthalene in the solid phase using chemical shift tensor information and the additivity of the electronic substituent effects.

Scheme 2. Possible conformations of methoxy group in 2-methoxynaphthalene.

5 STUDY OF STERIC EFFECTS ON CHEMICAL SHIFTS TENSORS

A classical example of this application is the study of the principal components of the ^{13}C chemical shift tensor in *cis*- and *trans*-butene. The experimental measurement of these principal components was presented in one of the earliest papers reporting ^{13}C chemical shift principal values at low temperature.¹² However, the assignment of the principal components into the molecular frame and their interpretation had to wait several years until adequate calculations of these chemical shifts became available.¹³ The calculated and experimental values of these tensors are displayed in Figure 2, where the calculations were used to assign the principal components into the molecular frame. From Figure 2 it becomes apparent that the γ steric effect is almost exclusively on the component perpendicular to the plane of the molecule, indicating that steric effects are observed in tensor principal components perpendicular to the plane in which the forces that generate the compression lie. The importance of the calculations becomes apparent when it is realized that the assignments in Figure 2 are not possible using only the experimental information. Moreover, the calculations can only provide a detailed analysis of the origin of the steric effect. The analysis of the localized bond contributions to the chemical shielding, in the local bond frame, reveals that the main contribution to the steric shielding effect in *cis*-butene originates in the compression of the C–C bond.¹⁴

6 SENSITIVITY OF THE CALCULATED SHIELDINGS TO THE MOLECULAR GEOMETRY

Calculations of chemical shieldings have been used to rationalize subtle results on the symmetry of the ^{13}C

Figure 2 $^{13}\text{CH}_3$ shift principal components in the molecular frame according to the LORG calculations in *cis*- and *trans*-butene. There is one component perpendicular to the plane of the paper in each molecule. The calculated values are given in parentheses. (Reproduced by permission of J. Wiley & Sons, Inc. from J. C. Facelli and D. M. Grant, in *Topics in Stereochemistry*, eds. E. L. Eliel and S. H. Wilen, 1989, Vol. 19, p. 1)

chemical shift tensors in naphthalene.¹⁵ The crystal of naphthalene belongs to the $P2_1/a$ space group which implies that the molecules have C_i symmetry. All the diffraction studies in naphthalene have been unable to resolve, outside of the experimental errors, any departure from the D_{2h} molecular symmetry observed for naphthalene in the gaseous or liquid phase. However, the ^{13}C chemical shift tensors of single crystal naphthalene exhibit C_i symmetry and the departures of the NMR results from D_{2h} symmetry are well above their experimental errors.¹⁶ This apparent contradiction between the experimental results obtained from diffraction and NMR techniques has been resolved by using calculations of the ^{13}C chemical shift tensors and their derivatives with respect to the geometrical parameters used in the calculations. Facelli and Grant in their 1993 paper¹⁵ calculated how sensitive the ^{13}C chemical shift tensors in naphthalene are to the molecular structure by evaluating the derivatives of the chemical shielding tensors with respect to all the independent parameters of the molecular structure of naphthalene. Using this information and standard techniques for the error propagation, they were able to demonstrate that the uncertainties in the diffraction data are large enough to cover the deviations from D_{2h} symmetry observed in the ^{13}C NMR data. That is, the chemical shift tensors present an intrinsic sensitivity to the molecular structure higher than diffraction methods. In Figure 3 a comparison is presented between the experimental and calculated chemical shift tensors in naphthalene and the errors introduced into the calculations by the uncertainties in the molecular structure. When these errors are taken into account, the agreement between the experimental and calculated chemical shift tensors is almost perfect. This high sensitivity of the chemical shift tensors to the molecular structure opens the exciting possibility of using chemical shielding information for quantitative structural

Figure 3 The excellent correlation between experimental and calculated ^{13}C chemical shift tensor components in naphthalene is shown. The error bars represent the uncertainties introduced into the calculations by the limited accuracy of the experimental geometry used in the calculation. (Reproduced by permission of Macmillan Magazines Ltd. from J. C. Facelli and D. M. Grant, *Nature (London)*, 1993, **365**, 325)

determination. It is important to realize that only tensor information of the chemical shieldings has the potential to give quantitative structural determination; the isotropic chemical shifts, which are also very sensitive to the molecular structure, do not provide enough data for solving the refinement problem which requires a minimum of $3N - 6$ independent measurements.

7 RELATIONSHIP BETWEEN CALCULATED ^{13}C CHEMICAL SHIFT TENSORS AND AROMATICITY

The concept of aromaticity has captured the imagination of chemists for more than a century. While the effect of aromaticity on many molecular properties is well understood, many questions remain on how to characterize the aromatic character of individual bonds. Most of the information regarding this question has been based on theoretical concepts derived from Kekulé resonance structures and/or more or less arbitrary definitions of electron populations derived from advanced molecular calculations.

The combined use of experimental measurements and calculations of chemical shift tensors in polycyclic aromatic compounds has provided a very interesting approach to the study of aromaticity. Facelli and Grant¹⁷ have developed a very simple model to calculate the in-plane principal components of the ^{13}C chemical shift tensors in polycyclic aromatic compounds using the Pople¹⁸ model for the chemical shielding and the MNDO¹⁹ approximation for wavefunction. In the limited cases in which experimental information is available, this theoretical method reproduces the in-plane components very well. The in-plane shielding components in these compounds are sensitive to the aromatic characteristics of the molecules, while the lowest-frequency (most upfield) component of the shift tensor, which is oriented perpendicular to the molecular plane, is determined by the σ -electronic structure. Although the experimental determination of ^{13}C chemical shift tensors in polycyclic compounds is extremely difficult due to the very long relaxation times of these compounds, a reliable computational method, which has been calibrated against all the existing experimental data, has allowed the study of a large number of ^{13}C chemical shift tensors in polycyclic compounds.

Our studies reveal that the in-plane anisotropy of the ^{13}C chemical shift tensors is determined by the differences in the aromatic character of the adjacent bonds. The direction of δ_{11} is along or close to the bond with the smaller bond order, i.e. the less aromatic. For protonated carbons this is always the C–H bond, but for quaternary carbons this can be any of the adjacent C–C bonds. Hence the orientation of δ_{11} and the difference between δ_{11} and δ_{22} give information on the aromatic character of the adjacent bonds. In Figure 4 we present the calculated values of δ_{11} and δ_{22} for the quaternary carbons of several polycyclic aromatic compounds.

Several important conclusions emerge from Figure 4. As is expected from arguments using the Kekulé structures of azulene, the large in-plane anisotropy of the quaternary carbon indicates that the central bond does not have any aromatic character. Triphenylene has an aromatic structure that more closely resembles the structure of three benzene rings connected by nonaromatic bonds than a four-membered ring

Figure 4 In-plane components of the ^{13}C chemical shift tensors of quaternary carbons in polycyclic aromatic compounds. These components have been calculated using the MNDO/Pople model proposed by Facelli and Grant.¹⁷ The orientation of δ_{11} and the asymmetry between δ_{11} and δ_{22} provide direct information on the aromatic character of the adjacent C–C bonds

system with π electrons delocalized over the whole molecule, and the structure of perylene is closer to the aromatic structure expected for two naphthalene molecules connected by two nonaromatic bonds.

8 CALCULATIONS OF CHEMICAL SHIFTS IN CARBOCATIONS

While the full power of a complete tensor analysis or even the measurement of the ^{13}C chemical shift principal values has not yet been applied to study the structure of carbocations, calculations of ^{13}C isotropic chemical shifts have been used successfully to determine the structure of these compounds. Early calculations of ^{13}C isotropic chemical shifts using the IGLO method²⁰ were in good agreement with the experimental values for the nonclassical ions, but differences of 20–30 ppm were observed for the classical ones. These results were originally interpreted as a deficiency of the IGLO method in calculating chemical shifts in carbocations, but later analysis²¹ indicated that deficiencies in the geometries of the carbocations used in the shielding calculations were responsible for the large discrepancies. In fact, when using carefully optimized ab initio geometries, the agreement between calculated and experimental chemical shifts becomes almost perfect for both classical and nonclassical carbocations, indicating that ^{13}C NMR in combination with quantum mechanical calculations could be used as one of the most effective tools for structural characterization of these compounds.

Figure 5 Correlation between the IGLO calculated ^{13}C chemical shifts and their experimental values in carbocations.²¹ The experimental values are referenced to TMS and the calculated to the absolute value calculated for TMS using the DZ (double zeta) basis set, 218.1 ppm. The best linear fit has a slope of 0.9544, an intercept of 3.94 ppm, R^2 value of 0.9973, and a standard marginal deviation of 5.24 ppm. This very low marginal standard deviation is characteristic of the results that can be obtained in chemical shift calculations when highly optimized ab initio geometrical structures are used in the ^{13}C chemical shifts calculations

This finding is of great importance because the structural characterization of carbocations has been an almost intractable problem. Note that standard structural techniques such as diffraction, microwave, or NOEs are not readily applicable to carbocations. On comparing the calculated ^{13}C chemical shifts for the possible structures of a carbocation with the experimental values of the chemical shifts it is possible to determine the structure of the carbocations in solution. Several important discoveries have been made in the carbocation field in recent years using this methodology and we expect that even more dramatic discoveries will be possible using the full tensor information. In Figure 5 we present the correlation between the experimental and the IGLO calculated chemical shift for several carbocations.²¹

9 ANGULAR DEPENDENCE OF THE PRINCIPAL COMPONENTS OF THE ^{13}C CHEMICAL SHIFT TENSORS

As discussed previously, our studies with *p*-tolyl ether indicate that the large differences between the δ_{22} components in the shift tensors of the aryl carbons directly bonded to the oxygen ether are of critical importance in making the corresponding chemical assignments of the NMR resonances. In this section we wish to reemphasize the importance of analyzing all the shielding components in any structural analysis. Several examples have been presented in the literature on how different components of the shielding tensors exhibit very different behavior with respect to geometrical parameters.²²

Carbon-13 chemical shift tensors can be used to extract valuable information on the structure of carbonaceous

materials.²³ To accomplish this goal it is necessary to develop a good understanding of the dependence of the chemical shielding on molecular structure. For this work, it is convenient to use model compounds that mimic the most common moieties present in coals. As an example, we have calculated the angular dependence of the principal values of the ^{13}C chemical shift tensors in diphenyl ether. In Figure 6 the angular dependence of the principal components is presented as a function of the ^{13}C OCC dihedral angle α , which is indicated in Scheme 1. It is remarkable that while δ_{11} and δ_{33} are almost independent of the dihedral angle, δ_{22} changes by more than 10 ppm over the whole range of α .

Figure 6 Calculated angular dependence of the ^{13}C chemical shift principal components of the phenyl carbon directly attached to the oxygen ether in diphenyl ether. The angle α is the dihedral angle between ^{13}C OCC as indicated in 1. The chemical shifts values are in ppm from TMS and the angle in degrees

10 CONCLUSIONS

The examples presented illustrate how important is the use of the full chemical shielding tensors in structural investigations and how the calculations of the tensors can complement the experimental measurements. In many cases calculations are mandatory to obtain information of any significance, but even in those cases in which the full tensorial data are available from experiments, the calculations provide invaluable information on the physical origins of the shielding and its relationship with the molecular structure.

We have only started using chemical shift tensor information to solve chemical and structural problems. As calculations improve, making possible the study of larger molecular systems, the use of experimental and calculated shielding information may become one of the most powerful tools available for molecular structure determination.

1 INTRODUCTION

The gauge-including atomic orbital (GIAO) method is a quantum mechanical technique for the calculation of magnetic properties of chemical systems. It is one of the main methods to solve the so-called gauge problem. In its simplest form, the latter is the unphysical dependence of the calculated results on the arbitrary gauge of the vector potential—in particular, the dependence on the position of the molecule if magnetic fields are present. In the GIAO method, the atomic basis functions depend explicitly on the magnetic field, canceling the gauge dependence of the results. Such basis functions were first used by London¹ to explain magnetic susceptibilities. They were introduced in modern electronic structure theory by Hameka² and Pople.^{3,4} Hameka^{2,5} also performed the first ab initio NMR shielding calculations using GIAOs, and coined the name ‘gauge-independent atomic orbital’ method. The name ‘gauge-including atomic orbital’ method is the usual one in the modern literature, since it retains the well-known GIAO acronym but it is more accurate. Some authors use the term ‘London atomic orbitals’ (LAOs) instead. GIAOs were first used in modern ab initio self-consistent field (SCF) perturbation theory by Ditchfield,⁶ who, with Ellis,⁷ performed the first applications to polyatomic molecules. Their early review is an excellent overview of the subject.⁸

As explained in more detail in the next section, the origin of the gauge problem is the truncation of the atomic orbital (AO) set used to describe the molecular orbitals (MOs). The perturbation caused by a homogeneous magnetic field B_z in the z direction is proportional to $B_z \hat{l}_z$, where $\hat{l}_z$ is the z component of the angular momentum operator. The latter is not invariant with respect to translations, and its effect on an atomic orbital is essentially an infinitesimal rotation of the orbital around the z axis. If the center of the orbital lies on the z axis, the perturbation leaves it either invariant (for an s orbital) or transforms it to another member of a degenerate set (e.g. p_x to p_y). However, for atomic orbitals centered far from the z axis, the (necessarily limited) AO basis set is usually not flexible enough to provide a satisfactory description of the perturbed wavefunction. This results in a progressively worsening description for atoms situated far from the origin, and is of course particularly serious for large molecules, which can now be treated with ab initio molecular orbital methods.

The most straightforward solution of this problem is to introduce a dependence in the atomic orbitals so that they provide the correct first-order solution to the atomic problem in a homogeneous magnetic field, irrespective of the position of the atom. This leads to the multiplication of the atomic orbitals by a complex exponential factor (*gauge factor*) that depends on the magnetic field, as well as the center coordinates of the AO and the Cartesian coordinates of the electron. Such a field-dependent basis set makes the evaluation of the dependence of the energy and wavefunction on the perturbation more complex, and also more expensive, compared with a fixed AO basis calculation of the same dimension. However, it allows the use of much smaller basis sets, and thus ultimately results in large savings. There are other techniques that restore gauge invariance. The most important of these [IGLO,⁹ independent gauge for localized orbitals (*Shielding Calculations: IGLO Method*), and LORG,¹⁰ localized orbital–local origin (*Shielding Calculations: IGLO Method*)] apply gauge factors not to atomic orbitals but to localized molecular orbitals. The success of IGLO, in particular, contributed much to renewed an interest in the ab initio calculation of chemical shieldings.

2 THE GAUGE PROBLEM AND THE DEFINITION OF GIAOs

According to nonrelativistic quantum theory, the momentum operator of an electron in the presence of a static magnetic field is^{11,12}

$$\hat{p} = -i\hbar\nabla + e\mathbf{A} \quad (1)$$

where i is the imaginary unit, $\hbar$ is Planck’s constant divided by 2π , $-e$ is the electron charge, ∇ is the symbolic vector of differentiation along the three spatial directions, and $\mathbf{A}$ is the vector potential of the electromagnetic field. [Note that we use the SI system of units; most older references use the Gaussian system, which differs not only in units but also in the dimensions and formulas, e.g. the second term on the right-hand side of equation (1) is divided by c , the speed of light, in the Gaussian system]. The vector potential $\mathbf{A}$ is related to the magnetic flux density $\mathbf{B}$ by

$$\mathbf{B} = \nabla \times \mathbf{A} \quad (2)$$

The gauge problem arises from the fact that $\mathbf{A}$ is not uniquely determined by $\mathbf{B}$. Addition of the gradient of any scalar function $f(\mathbf{r})$ to $\mathbf{A}$,

$$\mathbf{A}' = \mathbf{A} + \nabla f(\mathbf{r}) \quad (3)$$

leaves the flux density $\mathbf{B}$ and all other observable quantities unchanged, since $\nabla \times \nabla f = 0$. For homogeneous magnetic fields, the simplest choice of the vector potential is

$$\mathbf{A} = \frac{1}{2}\mathbf{B} \times \mathbf{r} \quad (4)$$

(Other choices, such as the Landau gauge¹¹ offer no advantage in the GIAO method). Choosing the scalar function $f = \frac{1}{2}\mathbf{B} \times \mathbf{r}_0 \cdot \mathbf{r}$ in equation (3) changes the vector potential to

$$\mathbf{A}' = \mathbf{A} + \nabla f = \frac{1}{2}\mathbf{B} \times (\mathbf{r} + \mathbf{r}_0) \quad (5)$$

which is equivalent to shifting the origin of the coordinate system to the new gauge origin $-\mathbf{r}_0$, or alternatively translating the molecule by $\mathbf{r}_0$ in the Cartesian frame.

It is easy to show that the gauge transformation, equation (3), does not change any observable results,^{11,12} by showing that simultaneously modifying the wavefunction as

$$\Psi' = \Psi \exp \left[-\frac{ie}{\hbar} \sum_i f(\mathbf{r}_i) \right] \quad (6)$$

transforms the Schrödinger equation, $\hat{H}\Psi = E\Psi$ to

$$\hat{H}'\Psi' = E\Psi' \quad (7)$$

In equations (6) and (7), $\mathbf{r}_i$ is the position of the i th electron and $\hat{H}'$ is the Hamiltonian in the new gauge. The transformation in equation (6) does not change any observable quantities; this is trivial for any local operators, since the wavefunction is merely multiplied by a phase factor. For the simple shift in the gauge origin, equation (5), the gauge factor for electron j is

$$\exp[-\frac{1}{2}i\mathbf{B} \cdot \mathbf{r}_0 \times \mathbf{r}_j] \quad (8)$$

where we have switched to atomic units ($\hbar = e = 1$).

Unfortunately, the invariance of the exact wavefunction under gauge transformations does not hold for most approximate methods—in particular, for those using finite basis set expansions. To understand the origin of this phenomenon, let us consider a one-electron central field (atomic) problem perturbed by a weak homogeneous magnetic field, described by the vector potential in equation (4). Substituting equation (1) into the Hamiltonian and changing to atomic units shows that the first-order perturbation is $\mathbf{B} \cdot \hat{\mathbf{l}}$, where $\hat{\mathbf{l}} = \mathbf{r} \times \hat{\mathbf{p}} = -i\hbar\mathbf{r} \times \nabla$ is the angular momentum operator. Only the first-order term, linear in $\mathbf{B}$, is needed for chemical shielding calculations. If the center (atom) is placed at the origin, the wavefunction can be chosen as an eigenfunction of the angular momentum operator, and therefore it remains an exact solution (to first order) in the presence of the magnetic field. If the atom is shifted to $\mathbf{r}_0$, the correct first-order wavefunction is simply the unperturbed wavefunction multiplied by the gauge factor in equation (8). For a field in the z direction, the first-order wavefunction can be approximately visualized as a rotation around the imaginary z axis. A finite basis set usually lacks the polarization functions needed to describe this rotation, leading to results that deteriorate as the atom moves away from the origin. This is only a cosmetic problem for atoms that have a natural gauge origin, but becomes acute in molecules, particularly large ones, since most atoms are necessarily far from the origin.

The most straightforward way to solve the gauge problem is to modify the atomic basis functions so that they remain the correct first-order eigenfunctions of the central field Hamiltonian for arbitrary positions in the presence of the field.¹ Such basis functions describe correctly a set of noninteracting atoms, and give greatly improved results for molecules, besides restoring translational invariance. The gauge-including atomic orbitals are defined, according to equation (8), as

$$\chi_p(\mathbf{B}) = \chi_p(0) \exp[-\frac{1}{2}i\mathbf{B} \cdot \mathbf{R}_p \times \mathbf{r}_i] \quad (9)$$

where $\chi_p(0)$ is an unperturbed atomic basis function and $\mathbf{R}_p$ is its center.

Integrals over GIAO basis functions are not origin-independent: a two-center integral (e.g. the overlap $\langle \chi_p | \chi_q \rangle$) is multiplied by the factor $\exp[-\frac{1}{2}i\mathbf{B} \times (\mathbf{R}_p - \mathbf{R}_q) \cdot \mathbf{d}]$ if the molecule moved by $\mathbf{d}$ in the Cartesian frame. Amos and Roberts,¹³ following London,¹ gave a simple proof of the translational invariance of the observables calculated from GIAO-based wavefunctions. The essence of this proof is that a simultaneous transformation of the molecular orbital coefficients C_{pi} to $C_{pi} \exp(\frac{1}{2}i\mathbf{B} \cdot \mathbf{R}_p \times \mathbf{d})$ cancels the translation dependence of the integrals and leaves all observable quantities invariant.

The position of the nucleus is the only natural choice for the gauge origin of the field generated by its magnetic dipole. As the dipole field diminishes rapidly (as r^{-3}) with distance, it is not necessary to consider alternative gauges.

For the widely used Gaussian-type basis functions (and also for Slater-type orbitals), the gauge factor can be formally absorbed into the coordinates of the center of the atomic orbital.¹⁴ The latter become field-dependent complex numbers. The advantage of such a viewpoint is that it emphasizes the analogy with the analytical derivative theory of potential surfaces.¹⁵ In spite of the difference in the physics, the mathematical descriptions are similar, the main difference being that the basis function centers remain real as they follow the nuclei in potential surface calculations, but they become complex in the presence of magnetic fields. Thus many of the highly developed techniques of analytical derivative theory can be used in GIAO calculations of magnetic properties.¹⁶

3 MOLECULAR ORBITAL THEORY WITH GIAOs

In this section, we shall consider *ab initio* (nonempirical) results only, since semiempirical methods have only been qualitatively successful.⁸ The magnetic shielding of a nucleus can be formally defined as the second derivative of the molecular energy with respect to the external magnetic field and the magnetic dipole moment of the nucleus. This is a dimensionless quantity with nine components, but usually only the six components of its symmetric part are accessible, and in nonoriented samples only the average of the diagonal elements is observed. The formal definition above is equivalent to the intuitive model in which the shielding is interpreted as the fractional change of the external magnetic field at the nuclear position due to induced currents in the molecule.

We begin with the most fundamental and widely used self-consistent field (SCF) approximation with a finite basis set. It is sufficient to consider only closed shell SCF theory, since this applies to the vast majority of molecules of interest in NMR. In the following formulas, we use superscripts for derivative quantities, the first of which corresponds to differentiation with respect to the external field, and the second (if present) to the nuclear magnetic moment.^{6,8} The subscript of the magnetic nucleus in question is not shown explicitly. Significant simplification is provided by the fact that only E_1 , the one-electron part of the total energy, depends on the nuclear magnetic moment. Thus the chemical shielding becomes, in the finite-basis closed shell SCF case,

$$\sigma^{ab} = \frac{\partial^2 E_1}{\partial B_a \partial \mu_b} = \text{Tr}[\mathbf{D}\mathbf{h}^{ab}] + \text{Tr}[\mathbf{D}^a \mathbf{h}^{0b}] \quad (10)$$

where σ is the chemical shielding, a and b are the x , y , z spatial directions, E_1 is the one-electron part of the total SCF energy, Tr stands for the trace of a matrix, $\mathbf{h}$ is the matrix of the one-electron operator (the sum of the kinetic energy and nuclear attraction) in the AO basis, $\mathbf{D}$ is the first-order reduced density matrix, $D_{pq} = 2\sum_i C_{pi}C_{qi}$, C_{pi} and C_{qi} are molecular orbital coefficients, p and q are AO indices, and i is an occupied MO. Equation (10) is simpler than the general SCF second-derivative formula (see, e.g. Pulay¹⁵), because the basis functions are independent of the second perturbation (with respect to the nuclear dipole moment). The evaluation of the derivative one-electron Hamiltonian matrix elements is simple, keeping in mind that the basis functions depend explicitly on the external magnetic field but not on the nuclear magnetic moments:

$$(\mathbf{h}^a)_{pq} = \langle p|\hat{h}^a|q\rangle + \langle p^a|\hat{h}|q\rangle + \langle p|\hat{h}|q^a\rangle \quad (11)$$

$$(\mathbf{h}^{0b})_{pq} = \langle p|\hat{h}^{0b}|q\rangle \quad (12)$$

$$(\mathbf{h}^{ab})_{pq} = \langle p|\hat{h}^{ab}|q\rangle + \langle p^a|\hat{h}^{0b}|q\rangle + \langle p|\hat{h}^{0b}|q^a\rangle \quad (13)$$

Here p and q denote atomic orbitals, and the derivative operators in the above formulas are defined as

$$\hat{h}^a = -\frac{1}{2}i\mathbf{r} \times \nabla \quad (14)$$

$$\hat{h}^{0b} = -i\alpha^2 \frac{[(\mathbf{r} - \mathbf{R}) \times \nabla]_b}{|\mathbf{r} - \mathbf{R}|^3} \quad (15)$$

$$\hat{h}^{ba} = \frac{\alpha^2}{2} \frac{\mathbf{r} \cdot (\mathbf{r} - \mathbf{R})\delta_{ab} - r_a(\mathbf{r} - \mathbf{R})_b}{|\mathbf{r} - \mathbf{R}|^3} \quad (16)$$

with $\mathbf{R}$ denoting the position of the magnetic nucleus and α denoting the fine structure constant, i.e. the inverse velocity of light in atomic units ($\alpha \approx 1/137.035989$). Equations (15) and (16) follow from the vector potential of the magnetic dipole at the origin (e.g., see, Atkins¹⁷),

$$\mathbf{A} = \frac{\mu_0}{4\pi} \frac{\mathbf{m} \times \mathbf{r}}{r^3} \quad (17)$$

after converting to atomic units ($\alpha^2 = \mu_0 e^2 / 4\pi m_e a_0$, where μ_0 is the vacuum permeability).

The first-order perturbed density matrix $\mathbf{D}^a$ needed to evaluate the shielding tensor in equation (10) can be obtained from the solution of the coupled perturbed Hartree–Fock (CPHF) equations. The GIAO case differs from the simpler theory with perturbation-independent basis functions¹⁸ in that all AO integrals have nonvanishing derivatives with respect to the magnetic field. Hartree–Fock perturbation theory for nuclear coordinates¹⁹ is, however, analogous to the GIAO case, and can be used with little change.⁶ The most compact and computationally efficient way is to use a density-matrix-based AO formulation.¹⁶ Starting with the derivative of

the Hartree–Fock equations, we can express the first-order derivative density matrix as

$$\mathbf{D}^a = -\frac{1}{2}\mathbf{D}\mathbf{S}^a\mathbf{D} + \sum_{iv} (\varepsilon_i - \varepsilon_v)^{-1} \mathbf{C}_i^\dagger (\mathbf{F}^a - \varepsilon_i \mathbf{S}^a) \mathbf{C}_v (\mathbf{C}_i \mathbf{C}_v^\dagger - \mathbf{C}_v \mathbf{C}_i^\dagger) \quad (18)$$

where the superscript a denotes differentiation with respect to $\mathbf{B}_a$, $\mathbf{S}$ is the AO overlap matrix, $\mathbf{F}$ is the Fock matrix, and $\mathbf{C}_i$ and $\mathbf{C}_v$ are column vectors of occupied and virtual orbital coefficients, respectively. Equation (18) must be solved iteratively, because the first-order Fock matrix $\mathbf{F}^a$ depends on $\mathbf{D}^a$:

$$(\mathbf{F}^a)_{pq} = (\mathbf{h}^a)_{pq} + \sum_{rs} [(\mathbf{D}^a)_{rs} g_{pqrs} + (\mathbf{D})_{rs} g_{pqrs}^a] \quad (19)$$

Here $g_{pqrs} = (pq|rs) - \frac{1}{2}(ps|qr)$ is an unperturbed two-electron integral, and g^a is its derivative (due to the gauge factors) with respect to the field component a . The strategy to solve equations (18) and (19) efficiently has been discussed in detail.¹⁶ The most demanding computational task is the calculation of the two-electron integrals g and g^a and their contraction with the density matrix. (An alternative formulation that interchanges the roles of the two perturbations is not viable in most cases, because there are only three external field directions but $3N$ nuclear magnetic moments.)

Using direct SCF techniques,²⁰ i.e. by not storing but recalculating the AO integrals, the size of the molecules that can be calculated is limited only by computer time. The most impressive calculation so far is perhaps the evaluation of the chemical shifts in several isomers of C_{84} , using good quality (triple-zeta plus polarization) basis sets²¹ containing 1596 atomic basis functions.

It is useful to decompose the total shielding into diamagnetic and paramagnetic contributions, though this is not a unique procedure and different authors propose different decomposition schemes. The most common decomposition designates the first term on the right-hand side of equation (10) as the diamagnetic term and the second as the paramagnetic one. In an alternative decomposition, the contribution from the first term in equation (18) is counted as diamagnetic. Essentially all of the problems in calculating shielding constants arise from the paramagnetic contribution. For an atom at the origin, the diamagnetic contribution, say the zz component, is given, according to equations (10), (13), and (16), as the expectation value of the operator $\frac{1}{2}\alpha^2(r^2 - z^2)/r^3$, and thus the isotropic average is the expectation value of $\frac{1}{3}\alpha^2 r^{-1}$. As this is essentially the electron–nucleus attraction energy, it is very accurate (even with mediocre basis sets) and stable.

The equations above are quite different from the sum over excited states in the Ramsey equation. The latter, although the main conceptual tool for understanding NMR shieldings, is not advantageous for numerical calculations—mainly because it requires that all the excited states of the unperturbed system be known exactly. This is not the case in *ab initio* theory, and the summary effect of the excited states, hidden in the iterative equations (17) and (18), can be evaluated at much less cost than the sum over excited states.

SCF calculations, although quite successful, particularly for relative shifts, still suffer from the neglect of correlation. In order to achieve higher accuracy, electron correlation must

be included in the wavefunction. The best way of doing this depends on the electronic structure of the system. If correlation effects are not dominant, second-order perturbation Møller–Plesset perturbation theory (MP2) serves as a relatively inexpensive and well-defined technique. NMR chemical shieldings with GIAOs at the MP2 level have been formulated and implemented recently by Gauss.²² The theory is too complex to include here, but the method is practical and improves significantly upon the SCF results in difficult cases. Applicability of the MP2 method is limited at present by the substantially increased computational and storage requirements compared with the SCF method. It is likely that this method will be extended soon to higher orders of Møller–Plesset perturbation theory, and to coupled cluster wavefunctions, yielding very accurate results, although at considerable computational cost.

For very strongly correlated systems, like F_2 or ozone, the MP2 method fails. These systems require a genuine multiconfigurational description. An alternative method, very successful for other ground state properties, is to use modern density functional theory. No GIAO results were available at the time of writing, but the prospects appear promising.

Although methods that place the gauge factors not on atomic orbitals but on localized molecular orbitals (IGLO⁹ and LORG¹⁰) have been very successful—and, in principle (though not so far in practice), they should be more efficient—the GIAO method has certain advantages over them. First, there is evidence that GIAO calculations require somewhat smaller basis sets than IGLO for the same accuracy.¹⁶ Second, localization of molecular orbitals is not always unique, and some systems are genuinely delocalized. In such cases, localized theories may have somewhat ill-defined results. Third, although localized theories can also deal with electron correlation, it is more straightforward to include correlation in the GIAO approach.

4 APPLICATIONS OF THE GIAO METHOD

In this section, some selected chemical applications of GIAO calculations of NMR shieldings are summarized, mostly at the SCF level. Calculations have been performed with a variety of nuclei (e.g. 1H , ^{13}C , ^{15}N , ^{17}O , ^{19}F , ^{29}Si , ^{31}P , and ^{33}S) using the GIAO approach. We begin with a brief discussion of the comparison between experiment and theory. The definitive test of the accuracy of the chemical shift calculations is the determination of absolute chemical shieldings. Two main factors limit the accuracy of this comparison: environmental effects and nuclear motion. Most calculations are performed on isolated molecules at the equilibrium geometry. Absolute shieldings from gas phase measurements are largely free of environmental effects, but vibrational averaging effects remain, even at absolute zero. In the absence of experimental absolute chemical shieldings, the chemical shift anisotropy of the shielding tensor is the next best parameter to use for a comparison of theory and experiment. This parameter does not require referencing or bulk susceptibility corrections. The principal components of the chemical shielding tensor are generally obtained from solid state NMR measurements, preferably with the solid at very low temperature to minimize contributions from molecular motion. In this case, however, environmental effects, unless included in the calculations, may be significant. Vibrational (temperature)

and environmental effects also influence chemical shifts, although some cancellation of these is to be expected for chemically and structurally similar atoms. It is also possible to obtain a fortuitously accurate isotropic shielding value when the errors in the components of the shielding tensor cancel.

NMR chemical shieldings are often sensitive functions of the molecular geometry, and therefore accurate chemical shieldings require good geometries. The main problem with using experimental geometries is that their accuracy is randomly varying, depending on the method used and the molecule itself. Theoretical values, although their absolute accuracy is often not better, provide much more homogeneous data if a single method and basis set is used throughout. The accuracy of relative chemical shifts often improves significantly if accurate computed geometries are substituted for experimental ones.²³

The chemical shift anisotropy of the hydrogen atom in the water cluster $(H_2O)_{17}$ has been calculated to determine the efficiency and accuracy of the GIAO method applied to relatively large molecular systems.²⁴ Experimental NMR measurements have been made on ice at very low temperatures, 173–195 K, to determine the chemical shift anisotropy of the hydrogen atom.^{25–27} However, significantly different values of the chemical shift anisotropy (28.7 ± 1 , 28.5 ± 1 , 34 ± 4 , and 34.2 ± 1 ppm) were obtained. The chemical shielding anisotropy of the hydrogen atom in the central water molecule of the $(H_2O)_{17}$ cluster was calculated to be 35.17 ppm (a 6-311G + 1p + 1d basis set was used for all atoms) and 34.83 ppm (a 6-311G + 1p + 1d basis set was used for the central water molecule and the 4 molecules in the first hydration sphere, and a 4-31G basis set was used for the remaining 12 water molecules in the second hydration sphere). The results of the calculations support the higher experimental values. This study of ice, modeled with the $(H_2O)_{17}$ cluster, $(H_2O)_5$ cluster, and H_2O , showed the potential importance of considering solvent (i.e. environmental) effects in performing chemical shift calculations.

There is a potential problem that one should be aware of in the use of the GIAO technique to calculate 1H chemical shifts. Although the calculation of 1H chemical shifts is perhaps the easiest to perform, because the number of electrons is the smallest of any atom, the chemical shift range of 1H is concomitantly the smallest. Consequently, variation in the calculated results may not be sufficient to distinguish between protons in similar chemical environments. Another problem is that protons are usually located at the periphery of the molecule, and are sensitive to intermolecular interactions.

The application of the GIAO method to the study of the very important ^{13}C chemical shifts was illustrated in the mid-1970s in the review by Ditchfield and Ellis.⁸ A recent GIAO SCF study of the chemical shifts in a number of hydrocarbons yielded good agreement with experiment.²⁸ Calculations of the dihedral angle-dependent shieldings for *n*-octane reproduced the γ -*gauche* effect to within about 3 ppm.²⁹ Carbon-13 chemical shielding tensors in sugars have been measured experimentally by solid state NMR studies of single crystals and calculated using the GIAO method.³⁰ The theoretical results were found to be of sufficient accuracy to aid in making the assignments of resonances arising from very similar carbon atoms. The correlation between theoretical and experimental results suggests that subtle structural features can be addressed with an accuracy comparable to that obtained

with X-ray and neutron diffraction techniques. A similar study of crystalline naphthalene suggests that the use of solid state NMR together with GIAO calculations of ^{13}C chemical shifts can be used to refine structural parameters obtained from diffraction methods.³¹ The calculation of ^{13}C chemical shifts was used recently to verify the photolysis product of 7-oxo[2.2.1]hericene.³²

The principal components of the chemical shielding tensor in the imine moiety of benzyldeneaniline and all-*trans*-retinylidenebutylimine have been calculated with the GIAO method.³³ The theoretical results for ^{13}C and ^{15}N were found to be in good agreement with solid state NMR measurements. The GIAO method has been used to calculate the chemical shift tensors of oxygen, carbon, nitrogen, and hydrogen in a study of the hydration of a dipeptide, glycylglycine.³⁴ It was found that while the orientation of the shift tensors for oxygen, carbon, and nitrogen is affected very little by hydration, the change of the amide proton tensor is significant and appears to follow the orientation of the local hydrogen bonding of water. Perhaps the most elegant and far-reaching application of the GIAO method has been that of Oldfield, in which ^1H , ^{13}C , ^{15}N , and ^{19}F chemical shifts were calculated for proteins and used to analyze the secondary and tertiary structure of proteins and to probe protein electrostatics.³⁵ These results strongly suggest that calculated chemical shifts may provide a new method for structure refinement of proteins.

The chemical shielding parameters for the ^{29}Si nucleus in a variety of compounds have been calculated using the GIAO method.³⁶ Molecules were chosen for study for which low-temperature solid state NMR spectroscopy had been used to obtain the chemical shielding parameters. Again, good agreement was achieved between the theoretical and experimental values.

The chemical shielding tensor for ^{31}P in phosphine PH_3 , has been calculated using the GIAO method³⁷ at both the SCF and the MP2 levels. Large basis sets and the inclusion of electron correlation were necessary to obtain accurate results, particularly for the absolute shielding. This illustrates the fact that it is much more difficult to calculate accurate results for atoms with lone pairs than, for example, carbon. The NMR shielding depends sensitively on the hybridization of the lone pair, and minor inaccuracies in the hybridization may result in significant errors in the chemical shielding.

Calculated ^{31}P chemical shifts have been used as part of a study of the pH, temperature, and concentration dependences of the chemical shifts in disodium hydrogen phosphite and disodium fluorophosphate solutions.³⁸ The experimental and theoretical results suggest that changes in pH and temperature cause changes in the average PF, PH, and PO bond distances, which lead to changes in the NMR parameters. Sulfur-33 chemical shifts for carbon disulfide, dimethyl sulfide, dimethyl sulfoxide, dimethyl sulfone, and sulfate and thiosulfate ions have been calculated.¹⁶

An impressive chemical application of the GIAO method is the confirmation of the existence and structure of stable Al-I compounds.³⁹

1 INTRODUCTION

Nuclear shielding data offer microscopic information about the stereochemical and crystal structures of polymers, which in turn are important factors in understanding physical properties. Details of electronic structure can also be deduced from nuclear shielding data, and this is also important in controlling physical properties.¹ In order to obtain information about the electronic structure of polymers from nuclear shielding data, it is necessary to use a theoretical approach in addition to an experimental one.

In general, there are two possibilities for obtaining such information by theoretical methods. One is to use a fragment of polymer such as a dimer, trimer, etc. for theoretical calculations. Such an approach is useful, because the nuclear shielding is sometimes governed by the local electronic structure. However, there is doubt whether the electronic structure obtained from the model compound appropriately reproduces that of the polymer chain. Another approach is to employ directly an infinite polymer chain with a periodic structure. This leads to the application of the tight-binding (TB) molecular orbital approximation, which was developed in the field of solid state physics.² Its advantages are that it treats the polymer directly and that relatively long range intrachain interactions such as hydrogen bonding in the α -helix form of polypeptides can be easily taken into account.

In using the model compound approach, the electronic structure of large chains can be visualized by drawing the orbital energies associated with chains of increasing length. On the other hand, for an infinite polymer chain, the energy levels are built up as a continuous band structure. As the rotation about the bond is strongly restricted in solid polymers, the periodicity of the polymer chain is retained. From the point of view of calculating nuclear shielding, use of the TB model for calculations of the electronic structures of polymers has been successful. Here we describe the basic ideas for deducing the electronic structure and nuclear shielding of solid polymers by the TB approximation.

2 THEORETICAL ASPECTS OF ELECTRONIC STATE AND NUCLEAR SHIELDING IN SOLID POLYMERS

Polymers can be characterized by a possible periodicity in their conformational structure and a large number of electrons. In this system, the potential energy that an electron experiences is periodic. Periodic systems have the advantage of translational symmetry when compared with aperiodic systems. It is possible to exploit this symmetry in order to reduce to reasonable proportions the formidable task of computing the electronic states of an extended system. The TB molecular orbital model is employed to describe the electronic structure of linear periodic polymers within the framework of a 'linear combination of atomic orbitals' approximation for electronic eigenfunctions. By means of Bloch's theory,³ the eigenfunction $\Phi_n(k)$ for an electron at position r , belonging to the n th crystal orbital is given by

$$\Phi_n(k) = N^{-1/2} \sum_{j=-(N-1)/2}^{(N-1)/2} \sum_{v=1}^s e^{ijkb} C_{vn}(k) \phi_v(r - jb) \quad (1)$$

where k is the wavenumber, v is an orbital index for the j th cell, s is the total number of atomic orbitals in a given cell, N is the total number of cells considered, and b is the unit vector of translational symmetry. In equation (1) $\phi_v(r - jb)$ represents the v th atomic orbital in the j th cell and $C_{vn}(k)$ its expansion coefficient in the linear combination of atomic orbitals. The limits of k , within a given Brillouin zone, are $-\frac{1}{2}\pi$ and $\frac{1}{2}\pi$. Using equation (1), the total energy E of the polymer can be expressed as

$$E(k) = \frac{\text{occ}}{n} \langle \Psi_n(k) | \hat{\mathcal{H}} | \Psi_n(k) \rangle \quad (2)$$

where $\Psi_n(k)$ is the Slater determinant composed of the $\Phi_n(k)$. $\hat{\mathcal{H}}$ is the Hamiltonian, consisting of terms representing the kinetic energy, the potential energy of the electronic field of the polymer, and the electron repulsion energy. The advantage of equation (1) is that calculation of the electronic structure of an infinite polymer can be reduced to the calculation for a unit cell (monomer unit) interacting with all other unit cells, using the periodicity of the polymer.

In general, calculations on small molecules using ab initio MO methods can provide very satisfactory estimates of nuclear shielding.¹ For larger monomeric species, semiempirical molecular orbital calculations such as CNDO/2 and INDO/S are still the workhorses. The diagonal and off-diagonal elements of the Fock matrix, $F_{\mu\mu}$ and $F_{\mu\mu'}$, respectively, based on CNDO/2, are expressed as follows:

$$\begin{aligned} F_{\mu\mu}(k) = & -\frac{1}{2}(I_\mu + A_\mu) + \frac{1}{2}(1 - P_{\mu\mu})\gamma_{AA}^{00} \\ & + \sum_B \sum_{j=-M}^M (P_B - Z_B)\gamma_{AB}^{0j} \\ & + 2K_\pi \beta_A \sum_{j=1}^M S_{\mu\mu}^{0j} \cos kj - \sum_{j=1}^M \gamma_{AA}^{0j} P_{\mu\mu}^{-jR} \cos kj \end{aligned} \quad (3)$$

$$\begin{aligned} F_{\mu\mu'}(k) = & \frac{1}{2}K_\pi(\beta_A + \beta_B) \sum_{j=-M}^M S_{\mu\mu'}^{0j} e^{ikj} \\ & - \frac{1}{2} \sum_{j=-M}^M P_{\mu'\mu}^{-jR} \gamma_{AB}^{0j} e^{ikj} \end{aligned} \quad (4)$$

Figure 1 Electronic band structure of polyethylene with *trans* zigzag conformation calculated using CNDO/2 TB MO

where I_μ and A_μ are the ionization potential energy and electron affinity, respectively, γ_{AB} represents the Coulomb repulsion integral between the atomic orbital μ on atom A in the original cell and the atomic orbital μ' on atom B in the j th cell. $S_{\mu\mu'}^{0j}(k)$ is the overlap integral between the μ th atomic orbital in the original cell and the μ' th atomic orbital in the j th cell. $P_{\mu\mu'}$ is the bond order matrix, P_B is the electron density on atom B, $P_{\mu\mu'}^{-jR}$ is the bond order matrix between the μ th atomic orbital in the original cell and the μ' th atomic orbital in the $\pm j$ th cell, and Z_B is the core charge of atom B. K_π is a correction factor for the π - π electron interaction.^{4,5}

By solving the Fock matrix defined by equations (3) and (4), the expansion coefficients in equation (1) can be obtained. These expansion coefficients and energies are dependent on k , which leads to a band structure for the polymer chain. Figure 1 shows the calculated band structure of polyethylene with a *trans* zig-zag conformation. As only six valence electrons in a monomer unit cell are included in the calculation, the corresponding six valence bands can be seen in Figure 1. Calculation with model compounds gives discrete energy levels. In a series of homogeneous molecules, the number of energy levels increases with the molecular size, and correspondingly the separation between these energy levels decreases. For an infinite polymer chain, the energy level is a continuous band structure, as shown in Figure 1. The electronic structure of solid polymers is characterized by this band structure, with a dependence of the energy level on k .

The nuclear shielding for the various nuclei in a given macromolecule can be calculated from the electronic band structure obtained, $C_{vm}(k)$, and $E_n(k)$. In general, the nuclear shielding can be written as¹

$$\sigma = \sigma^d + \sigma^p + \sigma' \quad (5)$$

where σ^d and σ^p are diamagnetic and paramagnetic contributions, respectively, and σ' is the contribution from neighboring atoms. For a carbon atom, σ' is much less than 1 ppm, and can be considered negligible. Thus, σ can be estimated as the sum of σ^d and σ^p . Based on the TB MO, σ^d and σ^p are obtained

by the sum-over-states method as follows:⁵⁻⁷

$$\sigma_A^d(k) = \frac{\mu_0 e^2}{6\pi m_e^2} \sum_v^A \sum_{v'}^A P_{vv'}(k) \langle \phi_v(r) | r^{-1} | \phi_{v'}(r) \rangle \quad (6)$$

$$\begin{aligned} \sigma_{A,\alpha\beta}^p(k) = & -\frac{\mu_0 h^2 e^2}{4\pi m_e^2} \sum_m^{\text{occ}} \sum_n^{\text{unocc}} \sum_j^A \langle r^{-3} \rangle_{2p} ({}^1 E_m^n - {}^1 E_0)^{-1} \\ & \times \sum_j^B \sum_l^B [X(k, j, m, n, \beta, \gamma) X(l, m, n, \gamma, \alpha) \\ & - Y(j, m, n, \beta, \gamma) Y(l, n, m, \gamma, \alpha) \\ & + X(j, m, n, \gamma, \alpha) X(l, n, m, \beta, \gamma) \\ & - Y(j, m, n, \gamma, \alpha) Y(l, n, m, \beta, \gamma)] \end{aligned} \quad (7)$$

Here e is the charge and m_e the mass of the electron, μ_0 is the permeability of free space,

$$P_{vv'}(k) = \sum_m^{\text{occ}} C_{vm}^*(k) C_{v'm}(k) \quad (8)$$

where m refers to the number of occupied crystal orbitals and n to those that are unoccupied, E_0 is the electronic energy of the ground state, and E_m^n is the energy of the state created by promoting an electron from orbital m to orbital n . j and l are atomic orbitals on centers A and B, respectively, and

$$X(j, m, n, \beta, \gamma) = C_{jm}^{\text{R}\beta} C_{jn}^{\text{I}\gamma} + C_{jn}^{\text{R}\beta} C_{jm}^{\text{I}\gamma} - C_{jn}^{\text{R}\gamma} C_{jm}^{\text{I}\beta} - C_{jm}^{\text{R}\gamma} C_{jn}^{\text{I}\beta} \quad (9)$$

$$Y(j, m, n, \beta, \gamma) = C_{jm}^{\text{R}\beta} C_{jn}^{\text{R}\gamma} + C_{jn}^{\text{R}\gamma} C_{jm}^{\text{R}\beta} - C_{jn}^{\text{I}\beta} C_{jm}^{\text{I}\gamma} - C_{jm}^{\text{I}\gamma} C_{jn}^{\text{I}\beta} \quad (10)$$

where α , β , and γ refer to the x , y , and z components of the shielding tensor in cyclic order, and R and I indicate the real and imaginary parts of the coefficients $C_{vm}(k)$. As shown by equations (6) and (7), the nuclear shielding is calculated as a function of k . In order to be able to compare the calculated and experimental values of the nuclear shielding, it is necessary to average the calculated data over k , within the first Brillouin zone, as given by

$$\sigma = \int_{-\pi/b}^{\pi/b} \sigma(k) D(k) dk \quad (11)$$

where $D(k)$ is the density of states, namely, the number of states per unit amount of energy. Thus, the nuclear shielding can be obtained through the electronic band structure of polymers—especially solid polymers.

The quantities calculated using equations (6) and (7) are nuclear shieldings σ , and so the negative sign means deshielding. On the other hand, a negative sign for the observed chemical shift δ means an increase in shielding. Hereinafter, calculated and observed shieldings are expressed as shielding and chemical shift, respectively. The absolute value of the calculated shielding should be compared directly with the observed chemical shift.

3 INTERPRETATION OF NUCLEAR SHIELDING BY THE TB METHOD

The shielding of ^{13}C reflects the magnetic environment of the atom considered, and this depends on the conformation, configuration, and crystal structure of polymers. In order to understand ^{13}C shielding, examples illustrating the applications of TB MO methods to some polymers will be described.

Figure 2 Dependence of the calculated ^{13}C NMR shielding of polyoxymethylene on dihedral angle ψ

3.1 Conformation

It is known from an X-ray diffraction study that a polyoxymethylene chain in the crystalline region takes an all-*gauche* conformation with a 9/5 helix.⁸ However, in the noncrystalline region, the structure has not yet been determined exactly, because of the complicated conformation of the chain. It has been reported that the observed ^{13}C chemical shifts of polyoxymethylene in crystalline and noncrystalline regions appear at 88.5 and 89.5 ppm, respectively.⁹ Figure 2 shows the dependence of the calculated isotropic ^{13}C shielding on the dihedral angles ψ within the framework of CNDO/2 TB MO.

The isotropic shielding of ^{13}C increases as ψ is increased from 50° to 90° , and the shielding decreases through a minimum value as ψ is increased from 90° to 180° . The values of 60° and 180° for ψ correspond to the all-*gauche* and all-*trans* conformations, respectively. The calculated isotropic ^{13}C shielding of the all-*gauche* conformation appears at lower frequency by about 1 ppm than that of the all-*trans* conformation. Dividing the difference of ^{13}C shielding between all-*gauche* and all-*trans* conformations, for the diamagnetic term, the difference between the all-*gauche* and all-*trans* conformations is 0.1 ppm, and for the paramagnetic term the corresponding difference is 0.9 ppm. The contribution to the relative ^{13}C shielding is due mainly to a change in the paramagnetic term. The diamagnetic term is determined only by the ground state, whereas the paramagnetic term involves interactions between the ground and excited states, as seen from equations (6) and (7). Thus, the observed chemical shift difference between the crystalline and noncrystalline regions

comes from a variable interaction due to a conformational change. Therefore, it can be argued that the calculated value confirms well the experimental finding that the ^{13}C shielding for the crystalline region is greater by about 1 ppm than that for the noncrystalline region.

Calculated values of $\Delta\sigma$ ($=\sigma_{yy} - \sigma_{zz}$; spectrum breadth) for the all-*gauche* and all-*trans* conformations are 37.7 and 1.8 ppm, respectively. $\Delta\sigma$ for the all-*gauche* conformation is much larger than that for the all-*trans* conformation. On the other hand, the experimental values of $\Delta\delta$ for the crystalline and noncrystalline regions are about 35 ppm and 7–10 ppm, respectively.⁹ The calculated and experimental values agree relatively well with each other. The fact that the calculated value of $\Delta\sigma$ for the all-*trans* conformation is rather small suggests that the electronic environment around the carbon nucleus considered here is relatively symmetric. The small observed value for $\Delta\delta$ may be due mainly to the high symmetry of the electronic environment in addition to the averaging of ^{13}C shielding anisotropy with molecular motion. Further, we are concerned with the behavior of δ_{22} , whose value is obtained from the apex of the tent-like powder pattern. In the experimental data, δ_{22} for the crystalline region appears at about 5 ppm to low frequency when compared with that for the noncrystalline region. However, the calculated value of σ_{xx} for the all-*gauche* conformation appears at lower frequency by about 2.5 ppm when compared with that for the all-*trans* conformation. Thus, the calculation explains the experimental observation reasonably, despite the rough assumption of an all-*trans* conformation for the noncrystalline region.

There has also been some interest in polypeptides. It has been demonstrated that the ^{13}C chemical shifts of C- α , C- β , and the carbonyl carbons are displaced by up to 7 ppm, depending on the particular conformations such as α -helix and β -sheet. Such conformation-dependent chemical shifts of ^{13}C can be understood through changes of the electronic band structure varying with the dihedral angles (ϕ and ψ) of the skeletal bond.

Table 1 shows the calculated and observed ^{13}C shieldings of a polyglycine chain with forms I and II.⁷ The observed carbonyl ^{13}C signal for form I is shielded by about 4 ppm compared with that for form II. The calculated ^{13}C shielding for form I is larger by about 11 ppm than that for form II, which matches the experimental finding. There is no significant difference between the methylene ^{13}C chemical shifts for forms I and II within experimental error. At this stage, it cannot be determined whether the methylene shielding for form I or that for II is the larger. The calculated shielding of ^{13}C for form I is smaller by about 3 ppm than that for form II, so the calculation predicts the existence of a shielding difference (about 3 ppm) between forms I and II. It appears that the calculated shieldings are somewhat exaggerated compared

Table 1 Observed and Calculated ^{13}C Chemical Shifts and Shieldings of an Isolated Polyglycine Chain

	δ_{obs} (ppm) ^a		δ_{calc} (ppm) ^b	
	Form I	Form II	Form I	Form II
CH ₂	43.5	43.5	-127.2	-124.4
C=O	168.4	172.3	-236.7	-248.1

^aFrom TMS. The positive sign means deshielding.

^bThe negative sign means deshielding.

with the observed values. Nevertheless, the observed trend that the ^{13}C chemical shift difference for the methylene carbon is very small when compared with that for carbonyl carbon is reproduced qualitatively by the calculation.

3.2 Configuration

Polyacetylene (PA) is the simplest conjugated polyene, and has two configurations (*cis* and *trans*). It has been reported that shielding of ^{13}C in *cis*-PA appears at lower frequency by about 10 ppm than that of *trans*-PA.¹⁰ Calculations of ^{13}C shielding in PAs have been carried out based on the use of CNDO/2 TB MO and INDO/S TB MO. The differences in the isotropic shielding of ^{13}C between *cis*- and *trans*-PAs, calculated using CNDO/2 and the INDO/S TB MO, are about 2.0 and 3.5 ppm, respectively,¹¹ i.e., the results differ by a factor of about 2. As the observed difference is about 10 ppm, both types of calculation somewhat underestimate the real values in this case.

Figure 3 shows the observed¹² and calculated components of the ^{13}C shielding tensors of *cis*- and *trans*-PA. As can be seen, the absolute values of σ_{zz} and σ_{xx} calculated using INDO/S TB MO are smaller by about 40 ppm than those obtained using CNDO/2 TB MO. The value of σ_{yy} calculated using INDO/S TB MO is larger by about 10 ppm than that obtained using CNDO/2 TB MO. Consequently, the separation between the values of σ_{xx} and σ_{yy} calculated using INDO/S TB MO is much larger than that obtained using CNDO/2 TB MO. Furthermore, it has been shown that in going from the calculation using CNDO/2 to that using INDO/S, the values of σ_{zz} and σ_{xx} are changed considerably. The most remarkable difference is the estimation of the π - π overlap integral. Values of σ_{zz} and σ_{xx} are affected by the distribution of π electrons.

The electronic band structure of a PA consists of five valence bands within the framework of the semiempirical method. The highest occupied band has π symmetry. Comparing the electronic band structures calculated using CNDO/2 TB MO with that using INDO/S TB MO, the energies of the three

high-energy bands increase, in particular that of the highest occupied band. As can be seen from Equation (5), σ^p contains a term proportional to the inverse of the excitation energy. The increase in the energies of the three high-energy bands is one of the factors leading to the deshielding of σ_{zz} and σ_{xx} , which implies a lower excitation energy. In fact, the band gaps (the energy difference between the highest occupied and the lowest unoccupied band) for *trans*-PA calculated using CNDO/2 and INDO/S TB MO are about 8.0 and 4.2 eV, respectively. The observed band gap for *trans*-PA is about 1.9 eV. Thus, the contribution of these high-energy bands to σ_{xx} and σ_{zz} is remarkably improved in going from CNDO/2 to INDO/S TB MO.

It is clear from Figure 3 that the reason why the calculated difference in isotropic shielding of ^{13}C between *cis*- and *trans*-PAs is underestimated is that the difference in σ_{yy} cannot be reasonably reproduced. In order to reproduce more reasonably the observed difference in σ_{yy} between *cis*- and *trans*-PAs, it may be necessary to use MOs that can properly describe band structures that have σ symmetry.

Polypyrrole is one of a series of heterocyclic polymers that has attracted much attention because of its characteristic electric and electronic properties. Fundamental structural formulas have been proposed for undoped and doped polypyrroles, where the aromatic form corresponds to the undoped state and the quinoid form to the doped state. From analysis of high-resolution solid state ^{15}N NMR, it is known that the ^{15}N chemical shift for the quinoid form appears to high frequency from that for the aromatic form. In order to obtain information about ^{15}N chemical shifts and electronic band structures of an infinite polypyrrole chain with aromatic or quinoid forms, calculations were carried out using INDO/S TB MO.¹³

As listed in Table 2, the calculated shielding of ^{15}N for the quinoid form appears to high frequency compared with that for the aromatic form. The calculated results agree with observed ones, suggesting that the electronic band structure has been properly estimated. From the calculated electronic band structure, the band gaps for the aromatic and quinoid forms are 5.1 and 2.9 eV, respectively. This result implies that the electrical conductivity of the quinoid form is larger than that of the aromatic form. Therefore, it can be expected that if the amount of the quinoid form is increased, polypyrrole with a higher electric conductivity can be obtained.

3.3 Crystal Structure

The crystal structure in the solid state, which describes how molecules condense, is an important factor when discussing physical properties. The effect of crystal structure on the nuclear shielding can, in principle, be separated from the effect of conformation and configuration to within the limitations of a quantum chemical model.

Experimentally, it is reported that the ^{13}C chemical shifts of the CH_2 carbon for *n*-paraffins, cyclic paraffins,

Figure 3 Observed and calculated components of ^{13}C NMR shielding tensors of *cis*- and *trans*-PAs. The directions of the principal axes are indicated at the bottom

Table 2 Calculated ^{15}N Shieldings and Band Gaps for Aromatic and Quinoid Polypyrrole Models Using INDO/S TB MO

Structure	Calculated shielding σ_{iso} (ppm)	Band gap (eV)
Aromatic	-223.50	5.12
Quinoid	-232.51	2.86

and polyethylene with *trans* zigzag conformations in the orthorhombic and triclinic forms are about 33 and 34 ppm, respectively.^{14,15} As the conformation is the same in each case, the difference of about 1 ppm may be due to a local change in intermolecular interactions resulting from the change of the orthorhombic to the triclinic form. Paraffins can be considered as models for the crystallographic form of the polyethylene. The results of X-ray diffraction studies suggest that the *trans* zigzag plane of any specified chain in the orthorhombic and triclinic forms is, respectively, perpendicular and parallel to that of the neighboring chains. The chemical shift of ^{13}C in polyethylene with a monoclinic form appears at higher frequency by 1.4 ppm compared with that of polyethylene with a orthorhombic form. The orientation of the *trans* zigzag plane in the monoclinic form is very close to that in the triclinic form.¹⁶ Thus, the solid state ^{13}C NMR chemical shift depends on the orientation of the C–C–C plane in the *trans* zigzag chains.

Since the chains lie periodically in space in the solid state, calculations of chemical shifts should be employed that take account of the three-dimensional structure, including interactions between chains. In order to take into account the interchain interaction, a ‘seven-polyethylene-chains model’ has been used to compute the ^{13}C shielding.¹⁷ Figure 4 shows models for polyethylenes with an orthorhombic form and

Figure 4 The ‘seven-polyethylene-chains’ model: (a) orthorhombic form; (b) monoclinic form

Figure 5 The ^{13}C NMR chemical shift difference between the orthorhombic and monoclinic polyethylene chains calculated using the seven-chains model, as functions of the setting angle ψ

a monoclinic form. The setting angle ψ for orthorhombic polyethylene is not clearly determined. Figure 5 shows the ψ dependence of the difference in shielding of ^{13}C between orthorhombic and monoclinic polyethylenes ($\sigma_{\text{orth}} - \sigma_{\text{mono}}$) calculated using INDO/S TB MO. As can be seen, the calculated difference in shielding of ^{13}C between these forms is positive in the case of $\psi = 25^\circ$ – 42° , and negative in the case of $\psi = 20^\circ$ – 25° and $\psi = 42^\circ$ – 55° . The largest difference occurs at $\psi = 35^\circ$. From these results, the angle of $\psi = 25^\circ$ – 42° is good for the setting angle of orthorhombic polyethylene, and can reasonably reproduce the observed data. This result shows that the difference in chemical shift between the orthorhombic and monoclinic forms is caused by the difference in interchain interaction through the electronic band structure.

The effect of crystal structure on the nuclear shielding of *cis*- and *trans*-PA is also relevant. A specified polymer chain is surrounded locally by six neighboring chains in the crystal, and these six chains can be separated into three groups. Each chain group consists of two chains, which are equivalent with respect to the central chain. In order to take interchain interaction into account, the ‘seven-chains model’ has been used to compute the ^{13}C shielding as shown in Figure 6.¹⁸

The calculated values depend on the chain arrangement. The total energies of *cis*- and *trans*-PAs show minima at $\Delta b = -10$ pm, where Δb is the deviation of b from the value determined by X-ray diffraction. A small decrease from the original crystal lattice values determined by X-ray methods leads to energetically stable results in the calculations for both PAs. This arises from the fact that CNDO/2 slightly underestimates the interaction distances, as is already known.¹⁹ However, an extreme decrease in the interchain distance leads to a large instability. Therefore, when comparing *cis*- and *trans*-PAs, it might be appropriate to consider the arrangement with a somewhat shorter distance. With respect to the band gap, the smaller the value of b , the smaller the band gap becomes. The decreases in the lattice parameters in the calculation correspond to the PA system under high pressure, where a shrinkage of the interchain distance occurs. It is therefore suggested that the electric conductivity of PA samples will increase with an increase in pressure. Comparing the isomers, the band gap value of *trans*-PA is smaller than that of *cis*-PA. This explains the experimental observation that *trans*-PA has a higher conductivity than *cis*-PA. The calculated values

Figure 6 Geometrical parameters of *cis*- and *trans*-PA: (a) valence geometries; (b) lattice parameters

are very large for the arrangement given by the original lattice parameters. The arrangement with a small value of b is near to the real form in the crystal. It has been shown experimentally that the lattice parameters a and b for *cis*-PA are larger than those for *trans*-PA (Figure 6); that is, the interchain distance of *cis*-PA is longer than that of *trans*-PA. This may be due to the different shapes of the PA chains. In the comb-like *cis*-PA chains, some of the hydrogen and carbon atoms tend to be very close in interatomic distance, and so they become repulsive (in fact, the nearest-neighbor C-H distance between the chains in *cis*-PA is shorter than that in *trans*-PA in the case using the original geometries). Therefore, the *cis*-PA crystal becomes more stable at the arrangement with the larger lattice parameters than does the *trans*-PA crystal, and these long interchain distances lead to a large band gap and so to a low conductivity for *cis*-PA.

Figure 7 shows the calculated dependence of the shielding of ^{13}C for *cis*- and *trans*-PA on Δb . In the arrangement with

Figure 7 Dependence on b of the calculated isotropic ^{13}C shielding of PA chains in the seven-chains model: $\circ$, *cis*; $\bullet$, *trans*

the original lattice parameters, the calculated values of σ_{iso} do not reproduce the observed large difference between the two isomers. However, in the arrangement with short interchain distances, the calculations agree well with the experiments. With regard to the chemical shift tensors, not only σ_{33} but also the components σ_{11} and σ_{22} decrease as the interchain distance is decreased. The most variable component for a change of the interchain distance is σ_{22} , whose direction is along that of the molecular chain. The effect of the interchain interactions might appear strongly in this direction. At $\Delta b = -100$ pm, the difference in σ_{22} between the isomers agrees quantitatively with the experimental data. From these results, the effect of crystal structure on nuclear shielding can be explained via the electronic structure in addition to the effect of the chain configuration.

1 INTRODUCTION

The analysis of a high-resolution spectrum requires that four questions be addressed. (i) What are the energy eigenvalues and eigenvectors of the system in a strong, stationary magnetic field $\mathbf{B}_0$? (ii) What are the selection rules governing transitions in the presence of perturbing magnetic fields? (iii) What are the relative intensities of allowed transitions? (iv) How can the parameters characterizing the system—the chemical shifts and coupling constants—be obtained from an experimental spectrum?

Although these questions are logically ordered from the spectroscopic point of view, experimentalists are principally interested in the structural information that can be derived from chemical shifts and coupling constants, since chemical shift data can be used to identify specific functional groups in many compounds, and coupling constants are often remarkably sensitive to the nature of the bonds between particular nuclei, such as the *cis*, *trans*, and geminal arrangements of protons about a carbon–carbon double bond.

The extraction of chemical shifts and coupling constants from an experimental spectrum is not always a simple matter, though with magnetic field strengths of 10 T or more most high-resolution spectra can be interpreted without much difficulty. In early high-resolution experiments, however, the analysis was almost invariably a difficult problem, since experiments were performed at field strengths of about 0.1 T when spin–spin interactions were comparable with differences in chemical shifts, leading to considerable fine structure. Furthermore, computers were not generally available to solve the algebraic equations of high degree often encountered with systems containing as few as four or five nuclei. Complex spectra occasionally arise even with the magnetic field strengths available today. This is always true for certain symmetrical molecules containing spin- $\frac{1}{2}$ nuclei with different magnetogyric ratios, such as 1,3,5-trifluorobenzene or 1,1-difluoroethylene. A somewhat similar consideration applies to certain symmetrical systems with nuclei having identical magnetogyric ratios, such as *o*-dichlorobenzene; although the spectrum is much simpler at 400 MHz than at 60 MHz, the

analysis at 400 MHz still requires some knowledge of the subtleties of high-resolution spectra. It is always possible to relegate such problems to the computer, but there are many instances where the analysis is so simple it can be carried out with little or no computation simply through familiarity with certain patterns that occur frequently in practice.

The following development presents a survey of some traditional methods of spectral analysis that eschews certain formal details that may be studied in monographs devoted to the subject.^{1–6} The reader is assumed to have some familiarity with quantum mechanics⁷ and the quantum theory of angular momentum.^{7–9}

2 THEORETICAL BASIS

2.1 Nuclear Angular Momentum

A charged macroscopic body spinning about an axis through it has a magnetic moment by virtue of the circulation of charge, angular momentum by virtue of the circulation of mass, and a straightforward classical calculation shows that the magnetic moment is proportional to the angular momentum. There is an analogous relation for nuclei, but quantum theory requires that the vector operator $\hat{\mu}$ representing the magnetic moment, be proportional to the vector operator $\hbar\hat{\mathbf{I}}$, representing the angular momentum:

$$\hat{\mu} = \gamma \hbar \hat{\mathbf{I}} \quad (1)$$

where $\hbar$ is Planck's constant divided by 2π , and γ , the magnetogyric ratio, is an empirical constant which may be positive or negative (Table 1). The dimensionless vector operator $\hat{\mathbf{I}} = (\hat{I}_x, \hat{I}_y, \hat{I}_z)$ represents the nuclear angular momentum in units of $\hbar$; its components are Hermitian operators satisfying

Table 1 Magnetic Resonance Data for Some Common Nuclei^{a,b}

³¹ P	$\frac{1}{2}$	1.1305	17.2347

^a μ_N is the nuclear Bohr magneton: $e\hbar/2m_p$.

^bThe natural units of ν are rad s⁻¹ T⁻¹; $|\nu|/2\pi$ is the (linear) resonance frequency in a field of 1 T.

$$[\hat{I}_x, \hat{I}_y] = i\hat{I}_z \quad (2)$$

$$[\hat{I}_y, \hat{I}_z] = i\hat{I}_x \quad (3)$$

$$[\hat{I}_z, \hat{I}_x] = i\hat{I}_y \quad (4)$$

where $[\hat{A}, \hat{B}] = \hat{A}\hat{B} - \hat{B}\hat{A}$ is the commutator of $\hat{A}$ and $\hat{B}$.

The square of the angular momentum (in units of $\hbar^2$) is

$$\hat{\mathbf{I}} \cdot \hat{\mathbf{I}} = \hat{I}^2 = \hat{I}_x^2 + \hat{I}_y^2 + \hat{I}_z^2 \quad (5)$$

which commutes with each component of $\hat{\mathbf{I}}$:

$$[\hat{I}^2, \hat{I}_x] = [\hat{I}^2, \hat{I}_y] = [\hat{I}^2, \hat{I}_z] = 0 \quad (6)$$

To prove these relations, first observe that $[\hat{I}^2, \hat{I}_x] = [\hat{I}_y^2, \hat{I}_x] + [\hat{I}_z^2, \hat{I}_x]$, since $[\hat{I}_x^2, \hat{I}_x] = 0$. The identity

$$[\hat{A}^2, \hat{B}] = \hat{A}[\hat{A}, \hat{B}] + [\hat{A}, \hat{B}]\hat{A} \quad (7)$$

together with equations (2) and (4) lead to the conclusion that $[\hat{I}^2, \hat{I}_x] = 0$. The others are proved similarly.

Equation (6) states that the scalar product $\hat{\mathbf{I}} \cdot \hat{\mathbf{I}} = \hat{I}^2$ is rotationally invariant, i.e. if $\hat{\mathbf{I}}'$ is the angular momentum referred to an $x'y'z'$ system related to the original xyz system by a rotation about the origin, then $\hat{\mathbf{I}}' \cdot \hat{\mathbf{I}}' = \hat{\mathbf{I}} \cdot \hat{\mathbf{I}}$. This is obvious for the scalar product of ordinary vectors which depends only upon the lengths of the vectors and their included angle, quantities independent of the coordinate system to which the vectors are referred. That the corresponding result holds for the scalar product of vector operators is a consequence of the fact that the components of $\hat{\mathbf{I}}$ are generators for rotations of the system space that correspond to physical rotations about the coordinate axes. Any rotationally invariant operator $\hat{V}$ associated with the nuclear angular momentum commutes with the components of $\hat{\mathbf{I}}$:

$$[\hat{V}, \hat{I}_x] = [\hat{V}, \hat{I}_y] = [\hat{V}, \hat{I}_z] = 0 \quad (8)$$

Rotational invariance has important implications for the theory of high-resolution spectra.

Since $\hat{I}^2$ and $\hat{I}_z$ commute, there exists a set of vectors each of which is an eigenvector of both operators. In fact, there are $2I + 1$ independent eigenvectors $\psi(I, m)$:

$$\hat{I}^2 \psi(I, m) = I(I + 1) \psi(I, m) \quad (9)$$

$$\hat{I}_z \psi(I, m) = m \psi(I, m) \quad (10)$$

where I is a non-negative integer, or half an odd positive integer, and $m = I, I - 1, \dots, -I + 1, -I$. Note that the argument of ψ is not the product of I and m , but a listing of the quantum numbers required to specify a state of angular momentum. For brevity, we omit punctuation between quantum numbers. When $I = \frac{1}{2}$, the two independent states of angular momentum will be denoted as

$$\alpha = \psi(\frac{1}{2}, \frac{1}{2}), \quad \beta = \psi(\frac{1}{2}, -\frac{1}{2}) \quad (11)$$

The eigenvalues of $\hat{I}_z$ are distinct, so the eigenvectors $\psi(I, m)$ are necessarily orthogonal. We shall assume they are also normalized:

$$(\psi(I, m'), \psi(I, m)) = \delta_{mm'} \quad (12)$$

where (ϕ, ψ) denotes the Hermitian scalar product of ϕ and ψ and $\delta_{m'm} = 1$ if $m = m'$, $\delta_{m'm} = 0$, if $m' \neq m$. In particular, when $I = \frac{1}{2}$:

$$(\alpha, \alpha) = (\beta, \beta) = 1 \quad (13)$$

$$(\alpha, \beta) = (\beta, \alpha) = 0 \quad (14)$$

The application of $\hat{I}_x$ or $\hat{I}_y$ to $\psi(I, m)$ can be inferred from the useful relations:

$$\hat{I}_{\pm} \psi(I, m) = \{(I \mp m)(I \pm m + 1)\}^{1/2} \psi(I, m \pm 1) \quad (15)$$

where the raising and lowering operators $\hat{I}_+$ and $\hat{I}_-$ are defined

by:

$$\hat{I}_{\pm} = \hat{I}_x \pm i \hat{I}_y \quad (16)$$

The following formulas for $I = \frac{1}{2}$ are used in many computations:

$$\hat{I}_z \alpha = \alpha/2, \quad \hat{I}_z \beta = -\beta/2 \quad (17)$$

$$\hat{I}_+ \beta = \alpha, \quad \hat{I}_- \alpha = \beta \quad (18)$$

$$\hat{I}_+ \alpha = \hat{I}_- \beta = 0 \quad (19)$$

2.2 Energy Levels and Selection Rules

The Hamiltonian operator for a nucleus in a magnetic field $\mathbf{B}$ is:

$$\hat{\mathcal{H}} = -\hat{\boldsymbol{\mu}} \cdot \mathbf{B} = -\gamma \hbar (B_x \hat{I}_x + B_y \hat{I}_y + B_z \hat{I}_z) \quad (20)$$

Now the product of the magnetogyric ratio and a magnetic field is an angular velocity whose significance may be deduced from the formula⁷

$$\frac{d}{dt}(\Psi, \hat{X} \Psi) = \left(\Psi, \frac{d\hat{X}}{dt} \Psi \right) \quad (21)$$

which states that the time derivative of the expectation value is equal to the expectation value of the time derivative. Taking $\hat{X}$ successively as $\hat{\mu}_x, \hat{\mu}_y, \hat{\mu}_z$ —which are not explicit functions of the time, so their partial derivatives with respect to t vanish—and making use of the Schrödinger equation

$$i\hbar \left(\frac{\partial \Psi}{\partial t} \right) = \hat{\mathcal{H}} \Psi \quad (22)$$

the results may be written in the vector form:

$$\frac{d}{dt} \langle \hat{\boldsymbol{\mu}} \rangle = -\gamma \mathbf{B} \times \langle \hat{\boldsymbol{\mu}} \rangle \quad (23)$$

This classical equation states that the expectation value of $\hat{\boldsymbol{\mu}}$ precesses about the instantaneous direction of $\mathbf{B}$ with angular frequency

$$\omega = -\gamma B \quad (24)$$

the sense of the precession being negative or positive according to whether γ is positive or negative. For a constant field, the trace of the vector $\langle \hat{\boldsymbol{\mu}} \rangle$ is a cone (Figure 1). A frequency proportional to the applied field is called a Larmor frequency.

In the special case of a nucleus with spin I in a stationary field $B_0 \mathbf{k}$, the Hamiltonian is

$$\hat{\mathcal{H}} = -\gamma \hbar B_0 \hat{I}_z \quad (25)$$

whose eigenvectors and eigenvalues are $\psi(I, m)$ and $E_m = -\gamma \hbar B_0 m$, $m = I, I - 1, I - 2, \dots, -I$. The levels are uniformly spaced, the spacing of successive levels being $\gamma \hbar B_0$ (Figure 2). Transitions between these levels can be induced by an oscillating radiofrequency field directed along the x axis:

$$B_x \mathbf{i} = 2B_1 \mathbf{i} \cos \omega t \quad (26)$$

where $B_1 \ll B_0$. Classically, the oscillating field exerts an additional torque on $\langle \hat{\boldsymbol{\mu}} \rangle$, which tends to increase the energy of

Figure 1 (a) The expectation value of $\hat{\mu}$ precesses about the field $\mathbf{B}$ with angular frequency $-\gamma B_0$. (b) The circle of precession drawn looking toward the xy plane from the positive z axis; the sense of precession is negative or positive according to whether γ is negative or positive

Figure 2 Energy levels of a nucleus with spin I in stationary field $B_0 k$

the system by increasing the angle between $\langle \hat{\mu} \rangle$ and $B_0 k$. This ‘flipping’ torque is most effective when the frequency of the oscillating field is equal to the Larmor precession frequency, that is, when $\omega = |\gamma| B_0$.

This result may be obtained quantum mechanically. According to first-order time-dependent perturbation theory, the oscillating field induces transitions between adjacent energy levels, i.e. the selection rule is $m' = m \pm 1$, or, equivalently, $\Delta m = \pm 1$. For $\Delta m = -1$, the system absorbs a single quantum of radiation from the oscillating field and the Bohr frequency rule requires that $E_{m'} - E_m = \hbar\omega$; substituting from $E_m = -\gamma \hbar B_0 m$, we find that $\omega = |\gamma| B_0$.

2.3 Chemical Shifts

The interaction of a nucleus bereft of enveloping electrons with an applied field $\mathbf{B}$ is given by equation (20), but this expression must be modified when the nucleus is embedded in a molecule since the field-induced motions of the electrons generate internal fields that also contribute to the field at the nucleus. The net field will, in general, differ from $\mathbf{B}$ in magnitude and direction, and will vary with molecular orientation. In fluid systems, where molecules experience random changes in orientation, the averaged induced field is proportional to the applied field: $\mathbf{B}_{\text{ind}} = -\sigma \mathbf{B}$, where the shielding constant σ is a positive number of the order of 10^{-5} for protons, varying roughly as $Z^{4/3}$ for nuclei with $Z > 1$ (see **Shielding: Overview of Theoretical Methods**).

The net field at the nucleus is $(1 - \sigma)\mathbf{B}$, so that if $\mathbf{B}_0$ is the field required for resonance with an unshielded nucleus, the field required for resonance when it is shielded must be increased to a value $\mathbf{B}_R$ such that $\mathbf{B}_0 = (1 - \sigma)\mathbf{B}_R$. This change

in the field required for resonance is called the chemical shift; it depends upon the electronic structure of the molecule, is generally different for the same nucleus in different molecules, and may even be different for the same nuclei in the same molecule, the difference in the field or frequency being then called the internal chemical shift. Internal chemical shifts distinguish structurally different nuclei in a molecule, hence their importance in chemical analysis.

In the averaging process mentioned above, it was tacitly assumed that the nucleus maintained its orientation with respect to the applied field, the molecule tumbling about it during the averaging process. A nucleus with $I > \frac{1}{2}$ possesses an electric quadrupole moment which interacts with the electric field gradient set up at the nucleus by the electrons, and this interaction can be strong enough that the orientation with respect to $\mathbf{B}$ is not maintained. In such instances, the lifetimes of nuclei in the states $\psi(I, m)$ can be so short that the resonance is too broad to detect. This does not, however, preclude consideration of spin quantum numbers $I > \frac{1}{2}$. For instance, deuterium ($I = 1$) has a relatively small quadrupole moment, and does not experience large field gradients. Moreover, nuclei with spin $\frac{1}{2}$ can, in certain circumstances, have their spins sum to values greater than $\frac{1}{2}$ but without the complications introduced by quadrupole interactions.

2.4 Spin-Spin Interactions

The analysis of a high-resolution spectrum would be a trivial matter if it was only necessary to take shielding effects into account: there would be one resonance for each distinct chemical environment, with an intensity proportional to the number of nuclei in that environment. Furthermore, the fourth column of Table 1, which gives the resonance frequencies for a field of 1 T, shows that different nuclei undergo resonance in different regions of the radiofrequency spectrum so there would be no interference from isotopes or other nuclei. There are, however, certain spin-spin interactions that survive the averaging processes characteristic of fluid systems, and these interactions, which must be rotationally invariant, generally produce considerable fine structure. The simplest interaction consistent with experiment is a scalar product of magnetic moments: $-K_{ij} \hat{\mu}_i \cdot \hat{\mu}_j$, where the proportionality constant, symmetric in i and j , depends upon the electronic structure of the molecule but is independent of the applied magnetic field. Introducing the spin vectors $\hat{\mathbf{I}}_i$, $\hat{\mathbf{I}}_j$, and defining the spin-spin coupling constant in Hz by

$$J_{ij} = (2\pi)^{-1} \gamma_i \gamma_j \hbar K_{ij} = J_{ji} \quad (27)$$

the interaction takes the standard form $-J_{ij} \hbar \hat{\mathbf{I}}_i \cdot \hat{\mathbf{I}}_j$. Representative values of spin-spin coupling constants are given in Table 2.

Table 2 Representative Values of Spin-Spin Coupling Constants

Molecule	Coupled nuclei	$ J $ (Hz)
H ₂	(H,H)	277
HD	(H,D)	43.5
CH ₄	(H,H)	12.4
¹³ CH ₄	(¹³ C,H)	125
PH ₃	(P,H)	179
PF ₃	(P,F)	1410

Taking into account the various chemical environments and all possible spin-spin interactions, the Hamiltonian operator in the field B_0 is given by

$$\hat{\mathcal{H}} = -h \left\{ \sum_i v_i \hat{I}_{zi} + \sum_{i < j} J_{ij} \hat{\mathbf{I}}_i \cdot \hat{\mathbf{I}}_j \right\} \quad (28)$$

where $v_i = |\gamma|(1 - \sigma_i)B_0/2\pi$, with σ_i being the averaged shielding constant for nucleus j . As nuclei with different magnetogyric ratios are generally observed in separate experiments, there is no loss of generality in assuming all nuclei in the system have the common magnetogyric ratio γ . The relative intensity of a transition conforming to the selection rule $m' = m - 1$ is proportional to the absolute square of the matrix element of $\hat{I}_-$ connecting the initial and final states:

$$\text{Int}(m \rightarrow m') = |\langle \phi(m'), \hat{I}_- \phi(m) \rangle|^2 \quad (29)$$

2.5 Multispin Systems

Any state of angular momentum for a nucleus of spin- $\frac{1}{2}$ may be written as a linear combination of α and β . The states of N spin- $\frac{1}{2}$ nuclei can be described by 2^N product functions, each factor in a product being α or β , the first factor referring to the first nucleus, the second factor to the second nucleus, and so on. If, for instance, $N = 4$, there are 16 such products: $\alpha\alpha\alpha\alpha, \alpha\alpha\alpha\beta, \alpha\alpha\beta\alpha$, etc., and any state of angular momentum can be expressed as a linear combination of these 16 product functions. These are not products in the arithmetical sense; the product notation is merely a convenient way of writing out a complete set of states for the system. The product functions for $N = 2, 3, 4$ are given in Table 3.

Each product function has a definite value for the net z component of angular momentum, equal to $m_T = (r - s)/2$, where r and s , respectively, denote the number of α s and β s. The number of product functions having the same value of m_T , which is equal to the number of ways $N = r + s$ objects can be divided into two groups having r and s objects in each group, is:

$$\eta(m_T) = \frac{N!}{(N/2 - m_T)!(N/2 + m_T)!} \quad (30)$$

Since α and β are orthonormal the product functions constructed from them are also orthonormal, the scalar product of product functions being equal to the product of individual

scalar products. For example, $(\alpha\beta, \beta\alpha) = (\alpha, \alpha)(\beta, \beta) = 0 \cdot 0 = 0$ and $(\alpha\beta, \alpha\beta) = (\alpha, \alpha)(\beta, \beta) = 1 \cdot 1 = 1$.

The spin vector for nucleus j is denoted $\hat{\mathbf{I}}_j = (\hat{I}_{jx}, \hat{I}_{jy}, \hat{I}_{jz})$; its components act only on the states of nucleus j and its components commute with the components of $\hat{\mathbf{I}}_k$:

$$[\hat{I}_{xj}, \hat{I}_{yk}] = i\hat{I}_{zj}\delta_{jk} \quad (31)$$

$$[\hat{I}_{yj}, \hat{I}_{zk}] = i\hat{I}_{xj}\delta_{jk} \quad (32)$$

$$[\hat{I}_{zj}, \hat{I}_{xk}] = i\hat{I}_{yj}\delta_{jk} \quad (33)$$

It is often essential in the consideration of a multispin system to compound several angular momenta to a resultant. In particular, two angular momenta $\hat{\mathbf{I}}_1, \hat{\mathbf{I}}_2$ may be compounded to a resultant $\hat{\mathbf{F}} = \hat{\mathbf{I}}_1 + \hat{\mathbf{I}}_2$, characterized by the total spin quantum numbers:

$$F = I_1 + I_2, \quad I_1 + I_2 - 1, \quad I_1 + I_2 - 2, \dots, \quad |I_1 - I_2| \quad (34)$$

For example, if $I_1 = I_2 = \frac{1}{2}$, the values of F are 1 and 0. The number of states corresponding to each value of F is $2F + 1$, so the total number of states in this case is $(2 \times 1 + 1) + (2 \times 0 + 1) = 4 = 2^2$.

To compute the values of F for three spin- $\frac{1}{2}$ nuclei, we add the third spin to the values of the total spin obtained when $N = 2$, obtaining $\frac{3}{2}, \frac{1}{2}$, the latter occurring twice, once as $\frac{3}{2} - 1$, and again as $0 + \frac{1}{2}$. The number of times a total spin quantum number appears is called the statistical weight and denoted g_F . The total number of states should be $2^3 = 8$, and on computing $2F + 1$ for $F = \frac{3}{2}, \frac{1}{2}$, taking into account that $g_{3/2} = 1, g_{1/2} = 2$, we find that there are indeed eight states.

The values of the total spin quantum numbers and their statistical weights resulting from the additional of several spin- $\frac{1}{2}$ nuclei are given in Table 4. These results are important in the study of systems composed of groups of magnetically equivalent nuclei.

The states corresponding to the various values of F are eigenvectors of the operators:

$$\begin{aligned} \hat{F}^2 &= (\hat{\mathbf{I}}_1 + \hat{\mathbf{I}}_2 + \dots)^2 \\ &= \sum_i \hat{I}_i^2 + 2 \sum_{i < j} \hat{\mathbf{I}}_i \cdot \hat{\mathbf{I}}_j \end{aligned} \quad (35)$$

Table 3 Product Functions for Spin $\frac{1}{2}$ Nuclei

Product function	m_T	$\eta(m_T)$
$\alpha\alpha$	1	1
$\alpha\beta, \beta\alpha$	0	2
$\beta\beta$	-1	1
$\alpha\alpha\alpha$	$\frac{3}{2}$	1
$\alpha\alpha\beta, \alpha\beta\alpha, \beta\alpha\alpha$	$\frac{1}{2}$	3
$\beta\beta\alpha, \beta\alpha\beta, \alpha\beta\beta$	$-\frac{1}{2}$	3
$\beta\beta\beta$	$-\frac{3}{2}$	1
$\alpha\alpha\alpha\alpha$	2	1
$\alpha\alpha\alpha\beta, \alpha\alpha\beta\alpha, \alpha\beta\alpha\alpha, \beta\alpha\alpha\alpha$	1	4
$\alpha\alpha\beta\beta, \alpha\beta\alpha\beta, \alpha\beta\beta\alpha, \beta\beta\alpha\alpha, \beta\alpha\beta\alpha, \beta\alpha\alpha\beta$	0	6
$\beta\beta\beta\alpha, \beta\beta\alpha\beta, \beta\alpha\beta\beta, \alpha\beta\beta\beta$	-1	4
$\beta\beta\beta\beta$	-2	1

Table 4 Total Spin Quantum Numbers for N Spin $\frac{1}{2}$ Nuclei

N	Total spin F	Statistical weight g_F
2	1 0	1 1
3	$\frac{3}{2}$ $\frac{1}{2}$	1 2
4	2 1 0	1 3 2
5	$\frac{5}{2}$ $\frac{3}{2}$ $\frac{1}{2}$	1 4 5
6	3 2 1 0	1 5 9 5

$$\hat{F}_z = \sum_i \hat{I}_{zi} \quad (36)$$

with the eigenvalues $F(F+1)$, $m_T = F, F-1, \dots, -F$, for each value of F in the sequence shown in equation (34).

3 ANALYSIS OF SIMPLE SPECTRA

3.1 The A_N System

The word *simple* is used here to characterize spectra that are simple in the sense that they exhibit only a single resonance, or simple in the sense that they can be described by the perturbation formulas of quantum mechanics. We shall begin with the first case—the A_N system—all of whose nuclei have the same Larmor frequency ν_0 , such as the protons in hydrogen, methane, and benzene. The protons in these molecules are symmetrically equivalent, as any one may be (conceptually) transformed into any other by a symmetry of the molecule, namely, a rotation, reflection, or inversion. Nuclei that are chemically equivalent by virtue of an exchange of positions through rapid internal motions will, in general, also have the same (averaged) Larmor frequency. Neopentane is an A_{12} system because of the relatively uninhibited rotations of the methyl groups about the bonds joining them to the central carbon atom.

The spectrum of an A_N system consists of a single line at the frequency ν_0 —even though the nuclei are coupled by spin–spin interactions of the form $J_{jk} \hat{I}_j \cdot \hat{I}_k$. The reason is that the equality of Larmor frequencies and the rotational invariance of spin–spin interactions result in the conservation of the square of the total spin angular momentum and the spin–spin interactions. To clarify the physical ideas, consider a magnetic resonance experiment with fluorine atoms, when it is obvious only one resonance would be observed. Yet the fluorine nucleus contains nine protons and 10 neutrons whose spins couple to a resultant spin of $\frac{1}{2}$. The coupling of the nucleons does not lead to fine structure because a magnetic resonance experiment deals with the interactions of resultant magnetic moments with each other and with applied fields. An A_N system behaves similarly, in that the coupling of the nuclei with each other leads to resultant magnetic moments that interact with applied fields and each other, but produce no fine structure.

The theory is straightforward. The stationary Hamiltonian for an A_N system is

$$\hat{\mathcal{H}} = -h(\nu_0 \hat{F}_z + \hat{V}) \quad (37)$$

where $\hat{V}$ denotes the spin–spin interactions:

$$\hat{V} = \sum_{i < j} \sum J_{ij} \hat{I}_i \cdot \hat{I}_j \quad (38)$$

Since $\hat{V}$ is rotationally invariant, it commutes with $\hat{F}_x$, $\hat{F}_y$, $\hat{F}_z$, and, therefore, also with $\hat{F}^2$, so that states of the system are characterized by the eigenvalues E , m_T , ν , $F(F+1)$ of $\hat{H}$, $\hat{F}_z$, $\hat{V}$, and $\hat{F}^2$. Writing F rather than $F(F+1)$ for brevity, the eigenfunctions take the form $\psi(E\nu m_T F)$ and the energies are:

$$E = -h(\nu_0 m_T + \nu) \quad (39)$$

The time-dependent Hamiltonian is

$$\hat{\mathcal{H}}(t) = -h(\nu_0 \hat{F}_z + \hat{V} + 2B_1 \hat{F}_x \cos \omega t) \quad (40)$$

The shielding correction to the amplitude of the oscillating field has not been included in the Hamiltonian since $B_1 \ll B_0$. Evidently $\hat{V}$ and $\hat{F}^2$ commute with $\hat{\mathcal{H}}$, so these operators are conserved even in the presence of the oscillating field.

Conservation of $\hat{F}^2$ requires $F'(F'+1) = F(F+1)$; hence $F' = F$, since the total spin quantum number must be non-negative. Thus the allowed transitions are $\psi(E\nu m_T F) \rightarrow \psi(E'\nu m_T' F)$ and the frequency of the transition is $\nu = (m_T - m_T')\nu_0$, which is independent of the spin–spin interactions. Thus, the energy levels between which transitions are allowed are shifted equally and in the same direction by the spin–spin interactions. The selection rule $\Delta m_T = -1$ now yields $\nu = \nu_0$.

A group of nuclei such that its total angular momentum and the spin–spin interactions within it are conserved is defined as a group of magnetically equivalent nuclei. The A_N system consists of a single group of magnetically equivalent nuclei and the interactions of the nuclei with each other cannot be observed. It is possible to estimate the coupling constants between magnetically equivalent nuclei by isotopic substitution. For example, the coupling constant between hydrogen and deuterium in HD is 43.5 Hz. Making the assumption that the substitution of deuterium for hydrogen does not alter the electronic structure significantly, the coupling in H_2 is obtained by multiplication with $\gamma_H/\gamma_D = 6.51$, which yields 277 Hz.

The concept of a group of magnetically equivalent nuclei can be generalized to systems with several groups $G = A, B, C, \dots$ of nuclei with Larmor frequencies $\nu_A, \nu_B, \nu_C, \dots$. A group S is a group of magnetically equivalent nuclei if the following conditions are satisfied:

$$\left. \begin{aligned} \nu_{Si} &= \nu_{Sj} = \dots \equiv \nu_S \\ J_{SiGr} &= J_{SjGr} = J_{SkGr} = \dots = J_{SGr} \\ r &= 1, 2, \dots, n_G \\ G &= A, B, \dots, \neq S \end{aligned} \right\} \quad (41)$$

where J_{SiGr} is the coupling constant for nucleus i in group S and nucleus r in group G . These conditions state that only one coupling constant is required to describe the interactions of group S with group G . If these conditions apply to the interactions of the nuclei in group G with those in group S , so that G is also a group of magnetically equivalent nuclei, the coupling between groups S and G can be described by a single coupling constant J_{SG} . When these conditions are satisfied, the total angular momentum and the spin–spin interactions within each group are conserved. The result is that the energy difference between any two levels for which a transition is allowed will be shifted by the same amount and in the same direction. It is permissible, therefore, to omit the interactions within magnetically equivalent groups from the Hamiltonian.

Groups of magnetically equivalent nuclei may be realized in practice by virtue of molecular symmetry, or an effective symmetry brought about by internal molecular motions. The protons adjacent to the chlorine atoms in 1,2,3-trichlorobenzene form a group of two magnetically equivalent nuclei as only a single coupling constant is required to describe the coupling to the third proton. Similarly, the protons in propane constitute an A_6B_2 system.

The stationary Hamiltonian for a system consisting of groups of magnetically equivalent nuclei is

$$\hat{\mathcal{H}} = -h \left(\sum_G \nu_G \hat{I}_{Gz} + \sum_G \sum_{G' < G} J_{GG'} \hat{I}_{G'} \cdot \hat{I}_G \right) \quad (42)$$

where the notation $G < G'$ means that G precedes G' alphabetically. The intensities of allowed transitions are given by the absolute squares of the matrix elements of¹

$$\hat{F} = \sum_G F_{G-} \quad (43)$$

connecting the initial and final states. The implications of magnetically equivalent groups in the analysis of high-resolution spectra will be discussed in Section 4.

3.2 Zero-Order Spectra

Zero-order spectra occur when the interactions of the nuclei are negligible compared with their interactions with the applied magnetic field. If the nuclei under consideration are divided into magnetically equivalent groups A, B, C, ..., containing $n_A, n_B, n_C, \dots$ spin- $\frac{1}{2}$ nuclei with the same magnetogyric ratio, the spectrum will consist, in general, of one line for each group with relative intensities in the ratios $n_A:n_B:n_C:\dots$. The proton spectrum of 1,1-dineopentyl-2-*t*-butylethylene (Figure 3) is an example. The *t*-butyl groups occupy structurally nonequivalent positions in the molecule, as exhibited by the three lines of equal intensity in the right side of the spectrum. (Further information would be required to assign a particular one of these resonances to the protons in a particular *t*-butyl group.) Similar remarks apply to the protons in the methylene groups. The remaining resonance is unambiguously identified as the olefinic proton. Four points should be particularly noted. (a) Rapid, internal rotations about carbon-carbon single bonds result in an averaging of local environments, leading to the structural equivalence of the protons in both the methylene and methyl groups. (b) Similar averaging processes lead to the structural equivalence of the methyl groups within each *t*-butyl group. (c) The

integrated signal intensities, as measured by the area under each resonance, are in the ratios 1:2:2:9:9:9. (d) Although the spectrum does not distinguish the individual *t*-butyl groups or methylene groups, the olefinic, methylene, and *t*-butyl groups are unambiguously identified.

3.3 First-Order Spectra

First-order spectra occur when spin-spin interactions introduce small corrections to the energy of the system in the applied field B_0 . Physically, two nuclei with magnetic moments interact by virtue of the electrons occupying intervening bonds, the result being that one nucleus experiences additional magnetic fields that vary with the orientation of the other with respect to field B_0 . Consider two spin- $\frac{1}{2}$ nuclei, A, X. In the absence of a spin-spin interaction, nucleus A experiences a (shielded) magnetic field along the z axis and the oscillating radiofrequency field generates a single resonance at the frequency ν_A . When A interacts with X, the z field at A will depend upon the orientation of nucleus X. In some molecules the z component of angular momentum for X will be parallel to the z axis, while in other molecules it will be antiparallel, the populations in these states being nearly equal according to the Boltzmann distribution. Nucleus A will thus exhibit two resonance lines of equal intensity equally shifted $|J_{AX}|/2$ above and below ν_A , so that the frequency separation of the lines is $|J_{AX}|$. As the interaction is reciprocal, X will also exhibit two resonance lines of equal intensity with frequency separation $|J_{AX}|$.

When there are n_A and n_X spin- $\frac{1}{2}$ nuclei in groups A and X, there will be $n_X + 1$ resonances for A with the common frequency separation $|J_{AX}|$ and with relative intensities

$$\binom{n_X}{n_X/2 + m_X}, \quad m_X = n_X/2, n_X/2 - 1, \dots, -n_X/2 \quad (44)$$

Similarly, there will be $n_A + 1$ resonances for X with the common frequency separation $|J_{AX}|$ and with relative intensities

$$\binom{n_A}{n_A/2 + m_A}, \quad m_A = n_A/2, n_A/2 - 1, \dots, -n_A/2 \quad (45)$$

The case $n_A = 1, n_X = 9$ is illustrated in Figure 4, which shows the ^{31}P resonances for trimethyl phosphite. Eight of the predicted 10 resonances are cleanly resolved; the remaining two lines are buried in the noise. The lines are uniformly spaced with $|J_{AX}| = 10.5$ Hz. The proton spectrum (not shown) consists of two lines of equal intensity with spacing 10.5 Hz. The first-order spectrum of the protons in diethyl ether at 400 MHz is shown in Figure 5.

3.4 Second-Order Spectra

The description of higher order spectra requires some rather tedious formal computations.¹ The following formulas for frequencies and intensities are obtained from the perturbation theory of quantum mechanics:

$$\begin{aligned} \nu_G + \sum_{G' \neq G} J_{GG'} m_{G'} + \frac{1}{2} \sum_{G' \neq G} \frac{J_{GG'}^2}{\nu_{GG'}} \{ F_{G'}(F_{G'} + 1) \\ - m_{G'}(m_{G'} + 1) + 2m_G m_{G'} \} \end{aligned} \quad (46)$$

Figure 3 The proton magnetic resonance spectrum of 1,1-dineopentyl-2-*t*-butylethylene at 60 MHz

Figure 4 The experimental (top) and theoretical (bottom) phosphorus magnetic resonance spectra of trimethyl phosphite at 23.4 MHz

Figure 5 The proton magnetic resonance spectrum of diethyl ether at 400 MHz. The multiplet spacings in the methyl triplet and the methylene quartet yield $J = 7.02$ Hz. The chemical shift is 907.69 Hz, so $J/\delta = 0.008$

$$g_{F_G}(F_G - m_G + 1)(F_G + m_G) \left\{ 1 - \sum_{G' \neq G} \frac{2J_{GG'}m_G}{\nu_{GG'}} \right\} \prod_{G' \neq G} g_{F_{G'}} \quad (47)$$

where $G = A, B, C, \dots$ and where $\nu_{GG'} = \nu_G - \nu_{G'}$. The total spin quantum numbers F_G and $F_{G'}$ and their statistical weights are computed by the procedure described in Section 2.5. Note that the formulas for first-order spectra are obtained by omitting the second summation in the formula for the frequencies, and omitting the second term within the curled brackets in the formula for the intensities.

For two groups A, B, the preceding formulas reduce to:

$$\nu_A + Jm_B + \frac{1}{2} \left(\frac{J^2}{\delta} \right) \{ F_B(F_B + 1) - m_B(m_B + 1) + 2m_A m_B \} \quad (48)$$

$$g_{F_A} g_{F_B} (F_A + m_A)(F_A - m_A + 1) \left(1 - \frac{2Jm_B}{\delta} \right) \quad (49)$$

The zero, first, and second-order spectra computed by perturbation theory are illustrated in Figure 6 for the A_3B_2 system.

In the case of the ABC system, i.e., three spin- $\frac{1}{2}$ nuclei, second-order perturbation theory yields the results given in

Figure 6 Zero, first, and second-order spectra for an A_3B_2 system

Table 5 Second-Order Perturbation Analysis of the ABC System^a

Frequency	Relative intensity
$\nu_A + \frac{1}{2}(J_{AB} + J_{AC}) + \frac{1}{4} \left(\frac{J_{AB}^2}{\nu_{AB}} + \frac{J_{AC}^2}{\nu_{AC}} \right)$	$1 - \frac{J_{AB}}{\nu_{AB}} - \frac{J_{AC}}{\nu_{AC}}$
$\nu_A + \frac{1}{2}(J_{AB} - J_{AC}) + \frac{1}{4} \left(\frac{J_{AB}^2}{\nu_{AB}} + \frac{J_{AC}^2}{\nu_{AC}} \right)$	$1 - \frac{J_{AB}}{\nu_{AB}} + \frac{J_{AC}}{\nu_{AC}}$
$\nu_A - \frac{1}{2}(J_{AB} - J_{AC}) + \frac{1}{4} \left(\frac{J_{AB}^2}{\nu_{AB}} + \frac{J_{AC}^2}{\nu_{AC}} \right)$	$1 + \frac{J_{AB}}{\nu_{AB}} - \frac{J_{AC}}{\nu_{AC}}$
$\nu_A - \frac{1}{2}(J_{AB} + J_{AC}) + \frac{1}{4} \left(\frac{J_{AB}^2}{\nu_{AB}} + \frac{J_{AC}^2}{\nu_{AC}} \right)$	$1 + \frac{J_{AB}}{\nu_{AB}} + \frac{J_{AC}}{\nu_{AC}}$

Here, and subsequently, $\nu_{AB} = \nu_A - \nu_B$, $\nu_{AC} = \nu_A - \nu_C$, etc.

Table 5. Twelve transitions are predicted; the frequencies and intensities of the remaining lines are obtained by cyclically permuting A, B, C. It should be noted that on changing the sign of each coupling constant the spectrum is transformed into itself. The same result holds for two-group systems, on recalling that to each value of m_B there is a corresponding value $-m_B$. Subject to the condition that the populations of the various levels are approximately equal, a high-resolution spectrum is independent of the signs of the coupling constants;¹ only the relative signs can be determined. When there is only one coupling constant we shall arbitrarily assume it to be positive.

The vinyl group protons in vinyl acetate at 60 MHz (Figure 7) provide an example of an ABC system to which second-order theory is applicable.

Figure 7 The proton magnetic resonance spectrum of the vinyl group protons in vinyl acetate at 60 MHz. The second-order spectrum was calculated for $\nu_{AB} = 18.71$ Hz, $\nu_{BC} = 146.09$ Hz, $|J_{AB}| = 1.45$ Hz, $|J_{AC}| = 6.37$ Hz, and $|J_{BC}| = 14.01$ Hz

4 STRONGLY COUPLED SYSTEMS

4.1 The AB System

The AB system consists of two spin- $\frac{1}{2}$ nuclei with the same magnetogyric ratio and resonance frequencies ν_A , ν_B in the absence of spin-spin interactions. We shall assume $\nu_A > \nu_B$, and write $\delta = \nu_A - \nu_B$ for the intramolecular (internal) chemical shift.

There are four independent states of angular momentum, so that operators will be represented by 4×4 matrices. As a basis we use the product functions $\alpha\alpha$, $\alpha\beta$, $\beta\alpha$, $\beta\beta$, writing the factors in alphabetical order. Operators referring to nucleus A operate only on the first factor of a product function; operators for nucleus B operate only on the second factor.

The stationary Hamiltonian operator is

$$\hat{\mathcal{H}} = -h(\nu_A \hat{I}_{Az} + \nu_B \hat{I}_{Bz} + J \hat{I}_A \cdot \hat{I}_B) \quad (50)$$

where for brevity we have written J for J_{AB} . The coupling operator $\hat{I}_A \cdot \hat{I}_B$ is rotationally invariant, so it commutes with $\hat{F}_z$. But the latter commutes with $\hat{I}_{Az}$ and $\hat{I}_{Bz}$, which implies $[\hat{\mathcal{H}}, \hat{F}_z] = 0$. Consequently, the matrix of $\hat{\mathcal{H}}$ relative to the product basis will be decomposed into three submatrices of dimensions 1×1 , 2×2 , 1×1 , corresponding to the eigenvalues 1, 0, 0, -1 of $\hat{F}_z$.

To compute the energy eigenvalues it proves convenient to write the interaction operator in terms of raising and lowering operators:

$$\hat{I}_A \cdot \hat{I}_B = \hat{I}_{Az} \hat{I}_{Bz} + \frac{1}{2}(\hat{I}_{A+} \hat{I}_{B-} + \hat{I}_{A-} \hat{I}_{B+}) \quad (51)$$

Operating on the product functions with $\hat{\mathcal{H}}$, we obtain:

$$\left. \begin{aligned} \hat{\mathcal{H}}\alpha\alpha &= -\frac{1}{2}(\nu_A + \nu_B + \frac{1}{2}J)\alpha\alpha \\ \hat{\mathcal{H}}\alpha\beta &= -\frac{1}{2}(\delta - \frac{1}{2}J)\alpha\beta - \frac{1}{2}J\beta\alpha \\ \hat{\mathcal{H}}\beta\alpha &= \frac{1}{2}(\delta + \frac{1}{2}J)\beta\alpha - \frac{1}{2}J\alpha\beta \\ \hat{\mathcal{H}}\beta\beta &= \frac{1}{2}(\nu_A + \nu_B - \frac{1}{2}J)\beta\beta \end{aligned} \right\} \quad (52)$$

Evidently, $\alpha\alpha$ and $\beta\beta$ are eigenvectors of $\hat{\mathcal{H}}$, but $\alpha\beta$ and $\beta\alpha$ are mixed by the interaction operator so that the remaining two eigenvectors are linear combinations of $\alpha\beta$ and $\beta\alpha$. The eigenvalues of these linear combinations are obtained by diagonalizing the 2×2 submatrix generated by $\alpha\beta$ and $\beta\alpha$:

$$\begin{pmatrix} -\delta + \frac{1}{2}J & -J \\ -J & \delta + \frac{1}{2}J \end{pmatrix}$$

The results of this computation are given in Table 6.

The selection rule $\Delta m_T = \Delta m_A + \Delta m_B = -1$ shows that transitions are allowed from each of the two states with $m_T = 0$ to the state with $m_T = -1$, and from the state with $m_T = 1$ to each of the states with $m_T = 0$. The resonance frequencies and relative intensities are computed using the formulas:

$$E_j - E_i = h\nu_{i \rightarrow j} \quad (53)$$

$$\text{Int}(i \rightarrow j) = |(\psi_j, (\hat{I}_{A-} + \hat{I}_{B-})\psi_i)|^2 \quad (54)$$

Table 6 ^aEigenvalues and Eigenvectors for the AB System

Eigenvector	m_T	Energy
1. $\alpha\alpha$	1	$-\frac{1}{2}(\nu_A + \nu_B + \frac{1}{2}J)$
2. $\frac{1}{(1+Q^2)^{1/2}} (Q\alpha\beta - \beta\alpha)$	0	$\frac{1}{2}(\frac{1}{2}J + R)$
3. $\frac{1}{(1+Q^2)^{1/2}} (\alpha\beta + Q\beta\alpha)$	0	$\frac{1}{2}(\frac{1}{2}J - R)$
4. $\beta\beta$	-1	$\frac{1}{2}(\nu_A + \nu_B - \frac{1}{2}J)$

$$^a Q = J/(\delta + R), R = (J^2 + \delta^2)^{1/2}.$$

where the ψ_i , $i = 1, 2, 3, 4$, are the eigenvectors of $\hat{\mathcal{H}}$ ordered as in Table 6. As an illustration we compute $\text{Int}(1 \rightarrow 2)$ and $\text{Int}(1 \rightarrow 3)$:

$$(\hat{I}_{A-} + \hat{I}_{B-})\psi_1 = \beta\alpha + \alpha\beta = (1 + Q^2)^{-1/2}[(Q - 1)\psi_2 + (Q + 1)\psi_3] \quad (55)$$

$$\text{Int}(1 \rightarrow 2) = \frac{(1 + Q)^2}{1 + Q^2} = 1 + J/R \quad (56)$$

$$\text{Int}(1 \rightarrow 3) = \frac{(1 - Q)^2}{1 + Q^2} = 1 - J/R \quad (57)$$

where

$$R = (J^2 + \delta^2)^{1/2}, \quad Q = \frac{J}{\delta + R} \quad (58)$$

The resonance frequencies and relative intensities are given in Table 7. Here, and subsequently, transitions denoted A are those for which $\Delta m_A = -1$ and $\Delta m_B = 0$ in the limit $J \rightarrow 0$; in this limit, the frequencies of A transitions approach ν_A . Similarly, B transitions for which $\Delta m_B = -1$, $\Delta m_A = 0$ as $J \rightarrow 0$, approach ν_B .

The spectrum consists of four lines and is symmetrical with respect to the mean resonance frequency, as indicated in Figure 8. The separations of the mean and extreme resonance frequencies may be used to compute the values of J and δ :

$$J = \frac{1}{2}[(A_1 - B_1) - (A_2 - B_2)], \quad \delta = [(A_1 - B_1)(A_2 - B_2)]^{1/2} \quad (59)$$

The proton spectrum of 2-bromo-5-chlorothiophene at 23.4 MHz is shown in Figure 9.

In the limit $\delta \rightarrow 0$, the AB system reduces to an A_2 system, the central lines coalesce, and the intensities of the outer lines decrease to zero. When δ is large compared with J , the AB system becomes an AX system with all four lines of equal intensity. The variation of the spectrum as J ranges from 0 to ∞ is shown in Figure 10.

Table 7 Frequencies and Intensities for the AB System

Transition ^a	Relative intensity	Frequency
A ₁	$1 - J/R$	$\frac{1}{2}(\nu_A + \nu_B + J + R)$
A ₂	$1 + J/R$	$\frac{1}{2}(\nu_A + \nu_B - J + R)$
B ₁	$1 + J/R$	$\frac{1}{2}(\nu_A + \nu_B + J - R)$
B ₂	$1 - J/R$	$\frac{1}{2}(\nu_A + \nu_B - J - R)$

^aHere, and subsequently, transitions denoted A, B are those having resonance frequencies at ν_A , ν_B , respectively, in the limit $J \rightarrow 0$.

Figure 8 The theoretical AB spectrum for $J/\delta = 0.5$

Figure 9 The proton magnetic resonance spectrum of 2-bromo-5-chlorothiophene at 23.4 MHz

4.2 The A_2B System

The A_2B system is the simplest system containing a nontrivial group of magnetically equivalent nuclei. The coupling within group A does not affect the spectrum, so it is not necessary to include it when making detailed calculations of the spectrum.¹ The results of the calculation are collected in Table 8, where

$$R_{\pm} = (\delta^2 \pm J\delta + \frac{9}{4}J^2)^{1/2} \quad Q_{\pm} = \frac{J\sqrt{2}}{\delta \pm \frac{1}{2}J + R_{\pm}} \quad (60)$$

Theoretical spectra are shown in Figures 11 and 12. The values of J and δ are given by the formulas

$$J = \frac{1}{3}\{(A_1 - A_4) + (B_1 - B_3)\}, \quad \delta = \frac{1}{2}\{(A_2 - B_4) + (A_3 - B_4)\} \quad (61)$$

The experimental spectrum of 1,2,3-trichlorobenzene at 60 MHz is shown in Figure 13. Eight of the nine predicted lines

Figure 10 Theoretical AB spectra for various values of J/δ

are cleanly resolved, leading to accurate determinations of J and δ . The ninth line, labeled M in Table 8, is a mixed transition, i.e., in the limit $J \rightarrow 0$, the resonance does not approach ν_A nor ν_B but $2\nu_A - \nu_B$, corresponding to the improbable triple spin flip $\alpha\alpha\beta \rightarrow \beta\beta\alpha$ for which $\Delta m_A = -2$, $\Delta m_B = +1$. The calculated intensities of mixed transitions are generally negligible in the spectra of two-group systems,¹ but this is not necessarily true for systems of three or more groups.

4.3 Irreducible Components

Analysis of a system containing any number of magnetically equivalent groups with at least one $n_G > 1$ can always be simplified by reduction into irreducible components defined by the total spin quantum numbers. The superposition of appropriately weighted subspectra generated by the irreducible components yields the theoretical spectrum. When the subspectra of previously analyzed irreducible components can be identified in the observed spectrum, the analysis can be materially simplified.

The fundamental idea is to identify the total spin quantum numbers and multiplicities of each magnetically equivalent

Table 8 Frequencies and Intensities for the A_2B System

Resonance	Intensity	Frequency
A ₁	$\frac{(\sqrt{2}-Q_-)^2}{1+Q_-^2}$	$\frac{1}{2}(\nu_A + \nu_B + \frac{3}{2}J + R_-)$
A ₂	$\frac{Q_-(\sqrt{2}Q_- - 1) + \sqrt{2}}{(1+Q_-^2)(1+Q_+^2)}$	$\frac{1}{2}(2\nu_A + R_+ - R_-)$
A ₃	$\frac{(\sqrt{2}+Q_-(1+\sqrt{2}Q_-))^2}{(1+Q_-^2)(1+Q_+^2)}$	$\frac{1}{2}(2\nu_A + \nu_B + R_- - R_+)$
A ₄	$\frac{(\sqrt{2}+Q_-)^2}{1+Q_-^2}$	$\frac{1}{2}(\nu_A + \nu_B + \frac{3}{2}J + R_+)$
B ₁	$\frac{(1+\sqrt{2}Q_-)^2}{1+Q_-^2}$	$\frac{1}{2}(\nu_A + \nu_B + \frac{3}{2}J - R_-)$
B ₂	$\frac{(\sqrt{2}(Q_- - Q_+) - 1)^2}{(1+Q_+^2)(1+Q_-^2)}$	$\frac{1}{2}(2\nu_A - R_+ - R_-)$
B ₃	$\frac{(\sqrt{2}+Q_+(1+\sqrt{2}Q_+))^2}{1+Q_+^2}$	$\frac{1}{2}(\nu_A + \nu_B + \frac{3}{2}J - R_+)$
B ₄	1	ν_B
M	$\frac{((Q_+ - \sqrt{2})Q_- + \sqrt{2}Q_+)^2}{(1+Q_+^2)(1+Q_-^2)}$	$\frac{1}{2}(2\nu_A + R_+ + R_-)$

Figure 11 Theoretical A_2B spectra for various values of J/δ

Figure 12 The theoretical A_2B spectrum for $J/\delta = 0.5$

group, assigning total spins in all possible ways to the various groups to form the irreducible component systems. The A_2B system provides the simplest example of a reducible spin system as $F_A = 1, 0$ and $F_B = \frac{1}{2}$ with $g_1 = g_0 = g_{1/2} = 1$. The spectrum of the A_2B system is thus the superposition of two irreducible components: $A_1B_{1/2}$ and $A_0B_{1/2}$, the latter consisting of a single line of unit intensity at ν_B . Thus, the decomposition may be symbolically written:

$$A_2B = A_1B_{1/2} + A_0B_{1/2} \quad (62)$$

In the general case, we can write:

$$A_{n_A}B_{n_B}C_{n_C} \dots = \sum_{\text{all } F_G} (g_{F_A} g_{F_B} g_{F_C} \dots) A_{F_A} B_{F_B} C_{F_C} \dots \quad (63)$$

where the product of the spin multiplicities is the number of times the irreducible component to which it is prefixed occurs in the decomposition. For example, the A_3B system has $F_A = \frac{3}{2}, \frac{1}{2}$ with $g_{3/2} = 1, g_{1/2} = 2$, and $F_B = \frac{1}{2}$ with $g_{1/2} = 1$, so that

$$A_3B = A_{3/2}B_{1/2} + 2A_{1/2}B_{1/2} \quad (64)$$

Thus the $A_{1/2}B_{1/2}$, which is just the (irreducible) AB system, occurs twice in the decomposition. If we can detect the AB

Figure 13 The proton magnetic resonance spectrum of 1,2,3-trichlorobenzene at 60 MHz. The theoretical spectrum was calculated with $J = 8.08$ Hz, $\delta = 13.97$ Hz

subspectrum in the observed spectrum, we can deduce the chemical shift and coupling constant without computing the spectrum of the irreducible $A_{3/2}B_{1/2}$ system.

As an illustration, consider the AB_2C system whose decomposition is

$$AB_2C = A_{1/2}B_1C_{1/2} + A_{1/2}B_0C_{1/2} \quad (65)$$

But $A_{1/2}B_0C_{1/2} \equiv A_{1/2}C_{1/2}$, since a system with spin zero does not have a magnetic moment and cannot, therefore, interact with internal or external fields. Identification of the $A_{1/2}C_{1/2}$ component in the experimental spectrum will yield $|J_{AC}|$ and ν_{AC} . The spectrum of *m*-dibromobenzene as observed at 60 MHz is shown in Figure 14, in which the irreducible $A_{1/2}C_{1/2}$ is identified by the consideration that for negligible coupling of nucleus C to A and to B the spectrum would be approximately that of an AB_2 system.

Referring to Table 4, we can deduce the following reduction of the A_3B_2 system into its irreducible components:

$$A_3B_2 = A_{3/2}B_1 + A_{3/2}B_0 + 2A_{1/2}B_1 + 2A_{1/2}B_0 \quad (66)$$

Here, the irreducible components with $F_B = 0$ generate a single, undeviated resonance at ν_A . If the $A_{1/2}B_1$ component can be identified, the coupling constant and ν_B can be determined from the known properties of that system. The application of this procedure to tetraethylsilane is illustrated in Figure 15.

When a system contains groups with an even number of spin- $\frac{1}{2}$ nuclei, the irreducible component for which all but one group, say group A, have their total spins equal to zero will generate a single line at ν_A . Similarly, the other

Figure 14 The proton magnetic resonance spectrum of *m*-dibromobenzene at 60 MHz, showing the irreducible $A_{1/2}C_{1/2}$ component with $|J_{AC}| = 0.30$ Hz and $\delta = 39.0$ Hz

Figure 15 The proton magnetic resonance spectrum of tetraethylsilane at 60 MHz: (a) experimental spectrum; (b)–(d) irreducible components; and (e) calculated composite spectrum. The horizontal axis is in Hz. Analysis of the irreducible components yields $J = 7.98$ Hz, $\delta = 24.91$ Hz

irreducible components will generate lines at each of the uncoupled Larmor frequencies. Identification of these lines in the spectrum will then yield all of the internal chemical shifts. Propane, an A_6B_2 system, is an example. The decomposition of the spectrum is shown in Figure 16. The coupling constant was determined from the properties of the A_2B_2 system.¹

4.4 Intensity Theorems

The intensity associated with a generic irreducible component is given by the formula

$$\text{Int}A_{F_A}B_{F_B}C_{F_C}\dots = \frac{2}{3} \left\{ \sum_G F_G(F_G + 1) \right\} \prod_G (2F_G + 1) \quad (67)$$

in which the sum and product are taken over all groups. Since the component $A_{F_A}B_{F_B}C_{F_C}\dots$ appears $g_{F_A}g_{F_B}g_{F_C}$ times in the reduction of the system, the contribution of all such systems to the total intensity of the system is $(g_{F_A}g_{F_B}g_{F_C}\dots)\text{Int}A_{F_A}B_{F_B}C_{F_C}\dots$. Using these formulas, it is possible to compute the contribution of a given irreducible component to the total relative intensity. For N particles with spins $I_1, I_2, \dots$, the total relative intensity is¹

$$\frac{2}{3} \prod_{i=1}^N (2I_i + 1) \left\{ \sum_{i=1}^N I_i(I_i + 1) \right\}$$

which reduces to $2^{N-1}N$ when all $I_i = \frac{1}{2}$. For example, the irreducible $A_{1/2}B_{1/2}$ component occurs 42-times in the A_9B system, such as isobutane, and contributes 3.28% to the total intensity.

5 THE X APPROXIMATION

5.1 The ABX_n System

Systems with several groups of magnetically equivalent nuclei A, B, C, ..., X admit an extremely useful approximation when ν_X is very different from $\nu_A, \nu_B, \nu_C, \dots$. The essential idea was implicit in the discussion of first-order spectra, when only the z components of angular momenta and their degeneracies were required for the analysis. In other words, the x and y components of the interaction involving $\hat{I}_X$ can be neglected, so that in the particular case of two groups A and X, the stationary Hamiltonian takes the form

$$\hat{\mathcal{H}} = -h(\nu_A \hat{I}_{Az} + \nu_X \hat{I}_{Xz} + J_{AX} \hat{I}_{Az} \hat{I}_{Xz}) \quad (68)$$

Since $\hat{I}_{Az}$ and $\hat{I}_{Xz}$ commute with $\hat{\mathcal{H}}$, states of the system can be chosen to be eigenvectors of these operators as well as

Figure 16 The proton magnetic resonance spectrum of propane at 60 MHz: (a) experimental spectrum; (b)–(e) irreducible components; and (f) calculated composite spectrum. Analysis of the irreducible components yields $J = 7.45$ Hz, $\delta = 26.32$ Hz

the Hamiltonian. For the validity of this approximation it is sufficient that $|\nu_{AX}| \ll |J_{AX}|$. The content of this condition is that states of very different energies can be treated by first-order perturbation theory.

The generalization of the preceding considerations presents no difficulties, but we shall consider only the case of three-group systems when the sufficient conditions for neglect of the x and y components of $J_{AX}\hat{I}_A \cdot \hat{I}_X$ and $J_{BX}\hat{I}_B \cdot \hat{I}_X$ are $|\nu_{AX}|, |\nu_{BX}| \gg |\nu_{AB}|, |J_{AB}|, |J_{AX}|, |J_{BX}|$. Excepting experiments at very low magnetic field strengths, these conditions will certainly be satisfied if $\gamma_X \neq \gamma_A = \gamma_B$. In any case, the stationary Hamiltonian is

$$\hat{\mathcal{H}} = -h(\nu_A\hat{I}_{Az} + \nu_B\hat{I}_{Bz} + \nu_X\hat{I}_{Xz} + J_{AB}\hat{I}_A \cdot \hat{I}_B + J_{AX}I_{Az}I_{Xz} + J_{BX}I_{Bz}I_{Xz}) \quad (69)$$

Since $\hat{I}_{Az} + \hat{I}_{Bz}$ and $\hat{I}_{Xz}$ both commute with $\hat{\mathcal{H}}$ and with each other, the eigenfunctions of the system will be eigenfunctions of $\hat{I}_{Az} + \hat{I}_{Bz}$, $\hat{I}_{Xz}$, and $\hat{\mathcal{H}}$. Taking the ABX_n system as a specific example, the product functions are of the form $\alpha\alpha\phi(F_X m_X)$, $\beta\beta\phi(F_X m_X)$, $\alpha\beta\phi(F_X m_X)$, $\beta\alpha\phi(F_X m_X)$. Only the last two products are coupled by the interaction $J_{AB}\hat{I}_A \cdot \hat{I}_B$, as these products have the same eigenvalue of $\hat{I}_{Az} + \hat{I}_{Bz}$, i.e. $m_A + m_B$.

The values of F_X and their statistical weights for n spin- $\frac{1}{2}$ nuclei may be determined by the procedure explained in Section 2.5, and the same procedure may be used to determine the corresponding values for nuclei with $I > \frac{1}{2}$, such as n deuterium atoms. The spectrum is worked out along the lines indicated for the AB system and the results are collected in Table 9, where:

$$R(m_X) = \{[\delta + (J_{AX} - J_{BX})m_X]^2 + J_{AB}^2\}^{1/2} \quad (70)$$

$$Q(m_X) = \frac{J_{AB}}{\delta + (J_{AX} - J_{BX})m_X + R(m_X)} \quad (71)$$

The complete spectrum is obtained for any value of n as follows. Starting with a particular value of F_X , we put $m_X = F_X, F_X - 1, \dots, -F_X$ in each of the tabulated A and B transitions, thus obtaining a total of $4(2F_X + 1)$ A and B transitions. For the X and M transitions, m_X only takes the $2F_X$ values, $F_X, F_X - 1, \dots, -F_X + 1$, for a total of $12F_X$ X and M transitions. Repeating this procedure for each value of F_X , the entire spectrum is generated.

It is important to recognize that the AB region of the spectrum consists of a superposition of AB systems and the identification of these AB quartets is an important key to the

Table 9 Frequencies and Intensities for the ABX_n System

Transition	Intensity	Frequency
A	$g_{F_X} \left(1 \pm \frac{J_{AB}}{R(m_X)}\right)$	$\frac{1}{2}\{\nu_A + \nu_B \mp J_{AB} + (J_{AX} + J_{BX})m_X + R(m_X)\}$
B	$g_{F_X} \left(1 \pm \frac{J_{AB}}{R(m_X)}\right)$	$\frac{1}{2}\{\nu_A + \nu_B \pm J_{AB} + (J_{AX} + J_{BX})m_X - R(m_X)\}$
X ₁	$\frac{g_{F_X}(F_X+m_X)(F_X-m_X+1)Q(m_X)Q(m_X-1)+1^2}{1+Q^2(m_X)+Q^2(m_X-1)}$	$\frac{1}{2}\{2\nu_X \pm R(m_X-1) \mp R(m_X)\}$
X ₂	$g_{F_X}(F_X+m_X)(F_X-m_X+1)$	$\frac{1}{2}(2\nu_X \pm J_{AX} \pm J_{BX})$
M	$\frac{g_{F_X}(F_X+m_X)(F_X-m_X+1)Q(m_X)-Q(m_X-1)^2}{1+Q^2(m_X)+Q^2(m_X-1)}$	$\frac{1}{2}\{2\nu_X \pm R(m_X-1) \pm R(m_X)\}$

analysis. On comparing the expressions for $R(m_X)$ and $Q(m_X)$ with those of R and Q for the AB system, we see that the apparent internal chemical shift, for a given value of m_X , is:

$$\nu_{AB}^* = |\delta + (J_{AX} - J_{BX})m_X| \quad (72)$$

Since these pseudo AB systems are symmetrical with respect to their mean resonance frequencies, the double quantum transitions for these systems can be used to identify their centers of symmetry¹ (see *Multiple Quantum Spectroscopy of Liquid Samples*). It should also be noted that the mixed transitions occur only in the X region of the spectrum.

5.2 The ABX System

For the ABX system $F_X = \frac{1}{2}$, so there will be eight AB transitions (two AB quartets), four X transitions, and two mixed transitions. The ABX system is often used to obtain a set of chemical shifts and coupling constants as initial parameters in an exact analysis of an ABC system. The spectrum of 2-fluoro-4,6-dichlorophenol, Figures 17 and 18, provides an excellent example of an ABX spectrum. The theoretical spectrum of the AB region shows the decomposition into (pseudo) AB quartets. The X region, Figure 18, shows the four X transitions and the two mixed transitions. The details of the analysis show that J_{AX} and J_{BX} are of opposite sign.

5.3 The ABX₂ System

For the ABX₂ system $F_X = 1, 0$, so there will be a total of 28 transitions: 12 AB transitions, 12 X transitions, and four mixed transitions. In particular, the AB region consists of three AB quartets: an actual AB quartet which occurs twice and two pseudo AB quartets each occurring once, with apparent internal chemical shifts

$$\nu_{AB}^* = |\delta + J_{AX} - J_{BX}| \quad (73)$$

$$\nu_{AB}^{**} = |\delta - J_{AX} + J_{BX}|. \quad (74)$$

The fact that the actual AB quartet appears with twice the relative intensity of the pseudo AB quartets may render its identification in an experimental trace easier.

The experimental and theoretical spectra of an approximately equimolar solution of *cis*- and *trans*-1,3-dichloropropene are shown in Figures 19 and 20. Both components conform to the ABX₂ approximation. Although the composite

experimental spectrum is somewhat complicated, there is sufficient resolution to disentangle the *cis* and *trans* isomers by

Figure 17 The proton magnetic resonance spectrum of 2-fluoro-4,6-dichlorophenol at 60 MHz. The parameters are in angular frequency units

Figure 18 The fluorine magnetic resonance spectrum of 2-fluoro-4,6-dichlorophenol at 56.4 MHz

Figure 19 Experimental and theoretical spectra of an approximately equimolar mixture of *cis*- and *trans*-1,3-dichloropropene at 400 MHz: the AB region (top); the calculated *trans* AB region (middle); and the calculated *cis* AB region (bottom)

virtue of the fact that couplings generally decrease in the order *trans* > *cis* > *gem*. This consideration leads to the separation of the isomers indicated in Figures 19 and 20. Taking the AB region of the *trans* isomer first, we recall that it should consist of 12 lines comprising three AB quartets, one of which is a true AB quartet that appears with twice the intensity of the pseudo AB quartets. The four lines of the true AB quartet are easily picked out and they lead at once to $|\nu_{AB}| = 103.36$ Hz, $|J_{AB}| = 13.19$ Hz. We can also easily pick out two of the lines belonging to the pseudo AB quartets in the high-frequency region of

Figure 20 Experimental and theoretical spectra of an approximately equimolar mixture of *cis*- and *trans*-1,3-dichloropropene at 400 MHz: the X region (top); the calculated *trans* X region (middle); and the calculated *cis* X region (bottom)

the spectrum: the first and third lines of the two triplets at high frequency constitute one pair, the third and sixth the other; but whichever pair of lines we choose, there are two choices for the other pair of lines of the quartet, depending on the relative signs of J_{AX} and J_{BX} . It turns out that the spectrum is independent of the sign of J_{AB} and, in the particular cases under consideration here, the spectra are independent of the relative signs of J_{AX} and J_{BX} . The magnitudes of these coupling constants for the *trans* isomer are $|J_{AX}| = 1.22$ Hz, $|J_{BX}| = 7.44$ Hz, and $|\nu_{AX}| = 918.8$ Hz, $|\nu_{BX}| = 815.4$ Hz. It should be noted that the coupling of the methylene protons (group X) to *trans* and geminal protons would be expected by first-order perturbation theory to split each of the lines of the AB quartet into triplets, and indeed the four triplets are evident in the AB region. A similar consideration applies to the *cis* isomer, but two lines of the low-frequency triplets overlap so that only 10 of the 12 AB lines are observed. An analysis similar to that for the *trans* isomer yields $|J_{AB}| = 7.25$ Hz, $|J_{AX}| = 1.08$ Hz, $|J_{BX}| = 7.38$ Hz, $|\nu_{AB}| = 90.8$ Hz, $|\nu_{AX}| = 803.61$ Hz, $|\nu_{BX}| = 712.83$ Hz.

6 SYMMETRICAL SYSTEMS

6.1 Symmetry Group of the Spin Hamiltonian

Analysis of symmetrical spin systems can be simplified through the use of group theoretical considerations, since each transformation in the symmetry group of the spin system commutes with the Hamiltonian. More precisely, the symmetry group of the spin system consists of those nonsingular operators $\hat{R}$ that leave the Hamiltonian invariant under a similarity transformation: $\hat{R} \hat{\mathcal{H}} \hat{R}^{-1} = \hat{\mathcal{H}}$. The symmetry group of the spin system is a subgroup of the symmetry

group of the molecule, where by 'symmetry group of the molecule' we mean the symmetry group of the molecule in its equilibrium configuration. As an illustration, consider the *o*-dichlorobenzene molecule (1) whose symmetry group consists of $\hat{E}$, the group identity, a twofold rotation $\hat{C}_2$, a reflection in the plane of the molecule σ_v , and σ_v' , a reflection in a plane through the rotation axis perpendicular to the plane of the molecule.

The symmetry of the molecule requires that $\nu_A = \nu_{A'}$, $\nu_B = \nu_{B'}$, $J_{AB} = J_{A'B'}$, $J_{AB'} = J_{A'B}$. On the other hand, the symmetry group of the spin system contains only two transformations, i.e. $\hat{E}$ and $\hat{C}_2$, as σ_v and σ_v' are equivalent to $\hat{E}$ and $\hat{C}_2$ insofar as the protons are concerned. The symmetry group of the molecule takes into account the electron distribution which contributes to the values of the shielding and coupling constants. Once the implications of the molecular symmetry group have been incorporated in the symmetry conditions imposed on the shielding and coupling constants, it is only necessary to consider the symmetry group of the nuclear spins, in this case the subgroup $\{\hat{E}, \hat{C}_2\}$.

Similar considerations apply to other molecules. Thus the molecular symmetry group of benzene is D_{6h} but the symmetry group of the protons is D_6 . In this case, however, no group theoretical calculations are required since the molecule consists of a single group of magnetically equivalent nuclei and only one resonance would be observed. With the identification of magnetic equivalence—a consequence of the conservation of angular momentum—the essential group theoretical considerations have been taken into account. Thus, the symmetry group of the protons in *m*-dibromobenzene (2), i.e.

is $\{\hat{E}, \hat{C}_2\}$, but as the protons denoted by the letter B are magnetically equivalent, it would be superfluous to carry out a group theoretical analysis of the system—the symmetry is taken into account by the conservation of angular momentum of group B. For these reasons, it is not necessary to appeal to group theoretical considerations in many instances where they might seem appropriate. There are, of course, instances where group theoretical considerations are quite useful, the case of *o*-dichlorobenzene being an example we shall consider in detail.

The basic idea in the application of group theory is that each operator in the symmetry group of the spin system commutes with the Hamiltonian operator, so that in the case of an Abelian group all operators in the group commute. Except for the identity operator, there will be additional nontrivial constants

of the motion (conserved quantities), and these will lead to further simplification of the Hamiltonian matrix. Moreover the operators of the group will also commute with the time dependent Hamiltonian, so there are additional symmetry restrictions on allowed transitions. Similar remarks apply to the case where the symmetry group of the spin system is non-Abelian, though in this case there will be fewer constants of the motion since not all of the group operators commute.

6.2 The AA'BB' System

The case of a molecule with spin symmetry $\{\hat{E}, \hat{C}_2\}$ is easily worked out. We have $[\hat{\mathcal{H}}, \hat{F}_z] = [\hat{\mathcal{H}}, \hat{C}_2] = 0$, so that it is possible to find a set of eigenvectors that are eigenvectors of $\hat{\mathcal{H}}$, $\hat{F}_z$, and $\hat{C}_2$.

Since $\hat{C}_2^2 = \hat{E}$, the eigenvalues of $\hat{C}_2$ satisfy $\lambda^2 = 1$, so that $\lambda = \pm 1$. If, therefore, we chose the initial basis vectors to be eigenvectors of $\hat{C}_2$, the Hamiltonian matrix will consist of two submatrices, one corresponding to the states with $\lambda = +1$ and the other to the states with $\lambda = -1$.

A symmetrized set of basis vectors may be constructed from the product basis by the application of projection operators, using the group character table which, in this case, is

	$\hat{E}$	$\hat{C}_2$
A	1	1
B	1	-1

The symmetrized basis vectors belonging to the irreducible representation, A, the symmetric representation, will be eigenvectors of $\hat{C}_2$ with $\lambda = +1$, whereas those belonging to B, the antisymmetric representation, will be eigenvectors of $\hat{C}_2$ with $\lambda = -1$. The projection operators are $\hat{E} + \hat{C}_2$ for the symmetric representation and $\hat{E} - \hat{C}_2$ for the antisymmetric representation, the coefficients for $\hat{E}$ and $\hat{C}_2$ having been taken from the character table. A symmetrized basis is obtained by applying these operators to each element in the product basis, retaining only the linearly independent vectors thus derived. The normalized vectors are given in Table 10, from which it is evident that the Hamiltonian matrix will consist of two submatrices, one a 10×10 matrix corresponding to $\lambda = +1$, the other a 6×6 matrix corresponding to $\lambda = -1$. To prove that these vectors are eigenvectors of $\hat{C}_2$, observe that if ψ is any product vector for which $(\hat{E} \pm \hat{C}_2)\psi \neq 0$, then

$$\hat{C}_2(\hat{E} \pm \hat{C}_2)\psi = (\hat{C}_2 \pm \hat{E})\psi = \pm(\hat{E} \pm \hat{C}_2)\psi \quad (75)$$

An alternative procedure for deriving a symmetrized basis for the AA'BB' system is to construct symmetrized vectors for the AA' nuclei and BB' nuclei separately, and then form their products. Applying the projection operators $\hat{E} \pm \hat{C}_2$ to the products $\alpha\alpha$, $\alpha\beta$, $\beta\alpha$, $\beta\beta$, we obtain the normalized basis vectors of Table 11. Using these vectors for the AA' and BB' nuclei, we obtain the basis vectors given in Table 12. A product belongs to the symmetric or antisymmetric representation according to whether the product of the $\hat{C}_2$ eigenvalues of the factors is +1 or -1. The advantage of this method is that each factor has definite eigenvalues of $\hat{I}_{Az} + \hat{I}_{A'z}$ and $\hat{I}_{Bz} + \hat{I}_{B'z}$ which will be useful in the discussion of the AA'XX' system.

Table 10 Symmetrized Basis Vectors for the AA'BB' System

Basis vector	$(S)_{m_T}$
$\alpha\alpha\alpha\alpha$	$(\mathcal{A})_2$
$\frac{1}{\sqrt{2}}(\alpha\alpha\alpha\beta + \alpha\alpha\beta\alpha)$	$1(\mathcal{A})_1$
$\frac{1}{\sqrt{2}}(\alpha\beta\alpha\alpha + \beta\alpha\alpha\alpha)$	$2(\mathcal{A})_1$
$\alpha\alpha\beta\beta$	$1(\mathcal{A})_0$
$\beta\beta\alpha\alpha$	$2(\mathcal{A})_0$
$\frac{1}{\sqrt{2}}(\alpha\beta\alpha\beta + \beta\alpha\beta\alpha)$	$3(\mathcal{A})_0$
$\frac{1}{\sqrt{2}}(\alpha\beta\beta\alpha + \beta\alpha\alpha\beta)$	$4(\mathcal{A})_0$
$\frac{1}{\sqrt{2}}(\alpha\beta\beta\beta + \beta\alpha\beta\beta)$	$1(\mathcal{A})_{-1}$
$\frac{1}{\sqrt{2}}(\beta\beta\alpha\beta + \beta\beta\beta\alpha)$	$2(\mathcal{A})_{-1}$
$\beta\beta\beta\beta$	$(\mathcal{A})_{-2}$
$\frac{1}{\sqrt{2}}(\alpha\alpha\alpha\beta - \alpha\alpha\beta\alpha)$	$1(\mathcal{B})_1$
$\frac{1}{\sqrt{2}}(\alpha\beta\alpha\alpha - \beta\alpha\alpha\alpha)$	$2(\mathcal{B})_1$
$\frac{1}{\sqrt{2}}(\alpha\beta\alpha\beta - \beta\alpha\beta\alpha)$	$1(\mathcal{B})_0$
$\frac{1}{\sqrt{2}}(\alpha\beta\beta\alpha - \beta\alpha\alpha\beta)$	$2(\mathcal{B})_0$
$\frac{1}{\sqrt{2}}(\alpha\beta\beta\beta - \beta\alpha\beta\beta)$	$1(\mathcal{B})_{-1}$
$\frac{1}{\sqrt{2}}(\beta\beta\alpha\beta - \beta\beta\beta\alpha)$	$2(\mathcal{B})_{-1}$

The analysis of an AA'BB' system requires the solution of an algebraic equation of the fourth degree in five parameters, and is best handled numerically (see *Analysis of Spectra: Automatic Methods*). Explicit expressions can be derived for 12 of the predicted 28 lines and these can be used to obtain a partial analysis. The spectrum of *o*-dichlorobenzene at 60 MHz is shown in Figure 21 in which the chemical shift and coupling constants are in angular units, hence the factors of 2π . The four lines shown separated by $L_+/2\pi = (J_{AB} + J_{AB'})/2\pi$ form a pseudo AB quartet which yields the values of $|\delta|$ and $|L_+|$. The spectrum of an AA'BB' system is symmetrical about the mean resonance frequency.

6.3 The AA'XX' System

When $|\delta| \rightarrow \infty$, all coupling constants remaining finite, the AA'BB' system becomes an AA'XX' system, and the X approximation yields considerable simplification of the problem. Of the four $(\mathcal{A})_0$ states, only $3(\mathcal{A})_0$ and $4(\mathcal{A})_0$ are mixed by spin-spin coupling, as these states have the same values of $m_{AA'}$ and $m_{XX'}$. The spectrum consists of 20 lines and Table 13 gives the 10 lines in the AA' region where

$$\begin{aligned}
 K_{\pm} &= J_{AA'} \pm J_{XX'}, & R_5 &= (K_+^2 + L_-^2)^{1/2} \\

Evidently, the resonances are symmetrically disposed about ν_A and the separation of the two most intense lines in the spectrum yields $|L_+|$. There is some ambiguity in the assignment of the remaining eight lines as they are grouped into pairs of lines whose intensities sum to 2. Furthermore, the spectrum is transformed into itself if the sign of $J_{XX'}$ is reversed, or if the sign of $J_{AA'}$ is reversed, so that at best one can only determine $|J_{AA'}|$, $|J_{XX'}|$, and $|L_-| = |J_{AX} - J_{AX'}|$.

The proton magnetic resonance spectrum of *o*-dichlorobenzene at 400 MHz is shown in Figure 22.

6.4 The A₂A₂'BB' System

Symmetrical systems containing magnetically equivalent groups can be decomposed into irreducible components. As an illustration, consider *trans*-1,4-dichloro-2-butene, an A₂A₂'BB' system. The components A₁A₀'B_{1/2}B_{1/2}' and

$\mathcal{B}_3$	$\frac{2}{1+Q_2^2}$	$\frac{1}{2}(2\nu_A - K_- + R_2)$
$\mathcal{B}_4$	$\frac{2Q_2^2}{1+Q_2^2}$	$\frac{1}{2}(2\nu_A - K_- - R_2)$

Figure 22 The high-frequency region of the proton magnetic resonance spectrum of 10% solution of *o*-dichlorobenzene in deuterated chloroform at 400 MHz (top), showing the high-frequency half of the symmetrical spectrum. The intense, single line at 98.65 Hz is a superposition of two virtually coincident lines. The theoretical spectrum (bottom) was reproduced with the coupling parameters derived from the 60 MHz spectrum (Figure 21) and an internal shift of 84.57 Hz. The frequency origin is at the symmetry center

$A_0A_1'B_{1/2}B_{1/2}'$ are clearly identical, so that the decomposition is $A_1A_1'B_{1/2}B_{1/2}' + 2A_1A_0'B_{1/2}B_{1/2}' + A_0A_0'B_{1/2}B_{1/2}'$.

In the $A_0A_0'B_{1/2}B_{1/2}'$ component, groups A and A' have zero total spin and are effectively decoupled from the other nuclei. Hence, this component yields a single line of four intensity units at ν_B . The spectrum of the component $A_1A_0'B_{1/2}B_{1/2}'$ is independent of $J_{AA'}$, depending only on ν_A , $J_{BB'}$, $J_{AB} \equiv J$, and $J_{AB'} \equiv J'$. Finally, the component $A_1A_1'B_{1/2}B_{1/2}'$ has C_2 symmetry, so that the states of the system may be classified as symmetric and antisymmetric. The experimental and theoretical spectra are shown in Figures 23 and 24.

7 OTHER APPROACHES

Modern, pulsed FT spectroscopy (see *Fourier Transform and Linear Prediction Methods*) provides additional opportunities for the simplification or analysis of complex high

Figure 23 Experimental and theoretical proton magnetic resonance spectra of the A_2A_2' region of *trans*-1,4-dichloro-2-butene at 60 MHz: (a) experimental spectrum; (b) symmetric transitions of the $A_1A_1'B_{1/2}B_{1/2}'$ component; (c) antisymmetric transitions of the $A_1A_1'B_{1/2}B_{1/2}'$ component; (d) $A_1A_0'B_{1/2}B_{1/2}'$ transitions; and (e) calculated composite spectrum

resolution spectra. The most elementary contribution is the availability of spectral information in digital form. Suitable resolution enhancement routinely available on modern spectrometers can resolve lines and eliminate ambiguities in assignments. Add/subtract software permits the removal of spectral lines from one component leaving the 'pure' second-order spectrum of another for analysis. All computers on modern FT systems contain programs to perform the calculations described above, initially as simulations and subsequently to obtain an iterative fit between simulated and experimental spectra. (Effective use of these programs requires some understanding of the material discussed here.)

More advanced techniques provide additional opportunities to simplify spectral analysis. For example, simple population transfer experiments such as INEPT (see *INEPT*) can be used to provide information about complex systems, particularly heteronuclear systems. Multiple quantum pulse techniques routinely used for filtering, solvent suppression, or coherence transfer may be applied to the multiple quantum analysis procedures described above. Homonuclear J -resolved 2D spectra (see *Two-Dimensional J-Resolved Spectroscopy*) as a minimum remove ambiguities arising from overlap of first or second order systems. Projection of these spectra provides what are effectively 'proton decoupled proton spectra', in which each chemically shifted species appears as a single line uncoupled to other protons. Thus, chemical shifts are immediately available for input to more complex analysis of the coupled systems. Second-order

Figure 24 Experimental and theoretical proton magnetic resonance spectra of the BB' region of *trans*-1,4-dichloro-2-butene at 60 MHz: (a) experimental spectrum; (b) symmetric transitions of the $A_1A_1'B_{1/2}B_{1/2}'$ components; (c) antisymmetric transitions of the $A_1A_1'B_{1/2}B_{1/2}'$ component; (d) $A_1A_0'B_{1/2}B_{1/2}'$ component; (e) $A_0A_0'B_{1/2}B_{1/2}'$ component, a single transition of four intensity units at ν_A ; and (f) composite calculated spectrum

systems also benefit from *J*-resolved 2D spectra where combination lines appear at appropriate offsets in both dimensions.

As magnetic field strengths have increased, providing greater sensitivity and simpler spectra, the size of molecules being studied has also increased. It is now common to obtain spectra which consist of a large number of relatively simple spectral elements (AB, ABX, AMX_2 , etc.) which are mixed together and/or overlapping. In some cases homonuclear COSY experiments (see *COSY Two-Dimensional Experiments*; *COSY Spectra: Quantitative Analysis*) provide critical information about which nuclei are coupled to each other, permitting applications of the principles discussed above to the identified subspectra without the need for more sophisticated analysis. They may also assist in determining which nuclei will or will not be included in more sophisticated analyses. Three-dimensional COSY experiments also permit the separation of otherwise complex overlapping systems into tractable subsets. For example, overlapping simple AB or ABX systems in peptides and proteins can be sorted on the basis of ^{15}N chemical shifts.

1 INTRODUCTION

The NMR spectrum itself is of little intrinsic interest: it is merely a stepping-stone to the parameters of analytical value—usually the chemical shifts and coupling constants, sometimes rate constants and relaxation times. For this reason the extraction of these parameters—the analysis of an NMR spectrum—plays a crucial role in the exploitation of the NMR method.

The synthesis of an NMR spectrum, i.e. its construction from given parameters using the well-known rules of quantum mechanics, may be tedious if the spin system is complex, but it is doomed to failure only if the problem is of a scale such that the rounding errors become significant or the calculation takes an inordinately long time. In contrast, the analysis of an NMR spectrum presents us with a task of such intricacy that only the simplest of spectra may be reduced to their parameters in a straightforward manner.

The reason for this dichotomy lies in the way in which the parameters are encoded into a spectrum, and to appreciate the problems involved in the decoding it is helpful to consider first how an NMR spectrum may be synthesized.

2 SPECTRAL SYNTHESIS

Using the spin system as a framework, we can construct a Hamiltonian operator as a function of the chemical shifts, coupling constants and so on:

$$\hat{\mathcal{H}} = f(\mathbf{p}) \quad (1)$$

where the parameters have been collected into a vector $\mathbf{p}$. Together with an appropriate set of basis functions $|\phi_i\rangle$, this operator may be employed to yield the Hamiltonian matrix $\mathbf{H}$ whose elements are

$$H_{ij} = \langle \phi_i | \hat{\mathcal{H}} | \phi_j \rangle \quad (2)$$

Diagonalization of the Hamiltonian matrix using standard numerical procedures yields the static energy levels of the spin system as eigenvalues, as well as the corresponding eigenvectors which represent transformations of the original basis to the stationary states of the Hamiltonian. It is now an easy matter to synthesize the NMR spectrum, for the transition frequencies are merely the differences of suitable eigenvalues and the intensities are simply related to the products of the corresponding eigenvectors.

3 NONAUTOMATIC ANALYSIS

One might expect that the wealth of information contained in an NMR spectrum and quantified into the frequencies and intensities of the transitions might both overdefine the parameters and pave an easy way to their determination. Whilst the former is certainly true (the spectrum of an ABC spin system for instance is characterized by three shifts and three couplings but provides 15 frequencies and 15 intensities), the latter is a delusion!

During the construction of the spectrum, the Hamiltonian matrix $\mathbf{H}$ is subjected to a similarity transformation to bring it into diagonal form

$$\tilde{\mathbf{U}}\mathbf{H}\mathbf{U} = \mathbf{D} \quad (3)$$

and whilst we can formally write

$$\mathbf{H} = \mathbf{U}\mathbf{D}\tilde{\mathbf{U}} \quad (4)$$

this equation is of little practical value since neither $\mathbf{D}$ nor $\mathbf{U}$ is known explicitly from the spectrum: all we can determine are the differences between certain elements of $\mathbf{D}$ and products of certain columns of $\mathbf{U}$. However, if the parameters are known reasonably well, a trial matrix $\mathbf{H}^{(0)}$ may be constructed and a trial spectrum calculated. From this, the true Hamiltonian matrix $\mathbf{H}$ may be obtained using perturbation theory,

$$\mathbf{H} = \mathbf{H}^{(0)} + \mathbf{H}^{(1)} \quad (5)$$

and provided $\mathbf{H}^{(1)}$ is small, its elements may be estimated from the differences in the frequencies of corresponding transitions in the experimental and synthetic spectra. This is the essence of the traditional method of iterative analysis exemplified by the programs NMREN/NMRIT of Swalen and Reilly¹ and the program LAOCOON of Castellano and Bothner-By.²

For these methods to work, however, it is necessary both that $\mathbf{H}^{(1)}$ be small enough for a linear approximation to hold, and that sufficient transitions in the synthetic spectrum be assigned to their experimental counterparts. This is the sticking point beyond which such methods fail.

4 SEMIAUTOMATIC ANALYSIS

Apart from some work on specific spin systems, the first serious attempt to automate the analysis generally is the contribution by Keller, Lusebrink, and Sederholm.³ They saw that two problems faced the user of the Swalen–Reilly method,

viz. the assignment of a sufficient number of experimental transitions and also the determination of the energy levels from these transitions.

The first problem was solved by the development of a program called DECOMP to identify overlapping lines, and the second problem by a program named ASSIGN which built up an energy level diagram in a systematic manner.

5 AUTOMATIC ANALYSIS

The real move into automatic analysis came, however, in the 1970s from two teams who sought a more general approach, and whose endeavors led to the computer programs STREAK and DAVINS.

5.1 STREAK

A decisive breakthrough was achieved by Diehl, Sýkora, and Vogt⁴ who realized that the information contained in a spectrum could be concentrated into a small number of data by means of an integral transform.

Anyone who has contemplated the spectrum of a molecule dissolved in a liquid crystal will appreciate the huge amount of information contained therein. An oriented eight spin- $\frac{1}{2}$ system gives rise to 11 440 transitions. Even with overlap a large number of these will be visible, and since the number of parameters which determine the spectrum (eight shifts, 28 isotropic couplings, and 28 anisotropic couplings) is only 64, the problem is obviously overdetermined. A parallel can well be drawn with the information content of a picture, and indeed for the storage and transmission of pictures several data compression techniques are available based on transformations.⁵

Specifically, Diehl et al. considered transforming both the experimental and synthetic spectra into small sets of real numbers which would then be compared with each other. Subsequently the parameters $\mathbf{p}$ could be varied so that the two sets converged. This approach has the advantage of avoiding the assignment step altogether and furthermore opening the prospect of allowing a solution starting from initial parameters far from their correct values—these are the two major stumbling-blocks in nonautomatic analysis.

This transformation of a spectrum is a very general concept but Diehl et al. restricted it somewhat by concentrating on linear integral transforms using orthogonal bases. This has certain technical advantages.

If the basis set is represented by the functions $w_k(\omega)$, then for each value of k the coefficient f_k , defined as the integral

$$f_k = \int_{-\infty}^{+\infty} w_k(\omega) I(\omega) d\omega \quad (6)$$

may be obtained from the spectrum $I(\omega)$, which can be either a stick spectrum (defined in terms of a sum of delta functions and thus fulfilling the integrability requirements) or as a regular array of intensities. The coefficients so obtained from the synthetic and experimental spectra may be used to form the functional

$$\Delta^2 = \sum_{k=1}^n (f_k^{\text{exp}} - f_k^{\text{syn}})^2 \quad (7)$$

and Δ^2 should then be reduced by varying the parameters using a standard optimization routine.

Diehl et al. originally considered several types of basis sets, but later⁶ restricted their choice to a Fourier basis together with a limited number of polynomials.

5.2 DAVINS

Stephenson and Binsch⁷ approached the problem from a different standpoint. Setting out from the lineshape analysis of NMR spectra broadened by chemical exchange,⁸ a project culminating in the iterative program DNMR5, they treated the high-resolution spectrum not as a set of sharp lines but as a vector of the spectral intensities measured at regular frequency intervals. This, of course, is ideally suited to the output of a modern NMR spectrometer and, indeed, in taking this step the problem of line assignment has been solved, for lines as such no longer exist!

There is certainly nothing new in fitting the lineshape of a high-resolution NMR spectrum. Glidewell, Rankin, and Sheldrick⁹ had shown that this was possible, and they also pointed out that although no assignment is necessary good trial values of the parameters are required. In their choice of examples these authors were lucky in taking compounds which had fairly well-known parameters and which in a field of 2.35 T yielded ^1H spectra showing relatively little fine structure. This made the analysis similar to that of an exchange-broadened spectrum.

In 1976, Heinzer¹⁰ also published work describing the application of lineshape fitting, and demonstrated the difficulties associated with local minima if the trial parameters are far from their true values.

The innovative idea of Stephenson and Binsch, however, is the recognition that local minima could be avoided by a modification of the error function. In this formulation a measured experimental spectrum is represented as a vector $\mathbf{s}$ whose elements are the intensities s_i at selected frequency values ω_i . Equally, the synthetic spectrum is a vector $\hat{\mathbf{s}}$ whose elements are functions of the parameters and the frequency:

$$\hat{s}_i = f(\mathbf{p}, \omega_i) \quad (8)$$

In the least-squares approach, the best estimate of $\mathbf{p}$ is that which minimizes the real functional

$$\phi = (\mathbf{s} - \hat{\mathbf{s}})^T (\mathbf{s} - \hat{\mathbf{s}}) \quad (9)$$

but whilst this is easy to state in principle, it is in practice no trivial task to obtain the unique vector $\mathbf{p}$. To see why this should be, consider the experimental doublet shown at the top of Figure 1, and the synthetic doublet shown below it. If the sole element of the parameter vector $\mathbf{p}$ consists of the chemical shift of the synthetic doublet, the error functional ϕ will have the form shown in the bottom curve of Figure 1—a global minimum where both lines overlap and a local minimum where one line overlaps. A standard minimization program starting from a shift out on the right will find the local minimum and then stop.

What we have to do is somehow tell the synthetic spectrum not to look straight up at the experimental but to take a glance

Figure 1 (a) Top: an experimental spectrum $\mathbf{s}$ consisting of a doublet. (b) Middle: a synthetic spectrum $\hat{\mathbf{s}}$ consisting of a doublet, the center frequency of which (ω) can move left or right. (c) Bottom: the error $\phi = (\mathbf{s} - \hat{\mathbf{s}})^T(\mathbf{s} - \hat{\mathbf{s}})$ as a function of the center frequency ω , showing a global and a local minimum

sideways, for only then will the true correlation between the synthetic and experimental spectra become obvious.

Now suppose we modify equation (9) to include a general square matrix $\mathbf{W}$:

$$\phi' = (\mathbf{s} - \hat{\mathbf{s}})^T \mathbf{W} (\mathbf{s} - \hat{\mathbf{s}}) \quad (10)$$

Then depending on the form of $\mathbf{W}$ and on the values of its individual elements, the functional ϕ' can be manipulated so as to smooth out the local minima. If this is achieved, the mixing of the residuals $(\mathbf{s} - \hat{\mathbf{s}})$ can be considered equivalent to introducing a pulling mechanism into the system, such that the lines in the experimental spectrum attract their counterparts in the synthetic. This attraction, at a distance, should be strong enough to overcome the direct local attraction which gives rise to local minima.

As an example, let us consider $\mathbf{W}$ to be a Toeplitz matrix whose elements are given by

$$W_{ij} = \exp(-\alpha|i - j|) \quad (11)$$

The effect on the two-line system is shown in Figure 2 for three values of α . Indeed, for a value of $\alpha < 0.02$, only one minimum exists and any simple optimization routine will be able to find it.

This two-line case does not fully represent the typical NMR spectrum, which can be better appreciated when we consider the ethyl group spectrum of ethylbenzene shown in Figure 3(a). The error surface defined by equation (9) is shown below the spectrum; in this case, both the linewidth and the coupling constant have been held fixed at their true values and the sole

Figure 2 (a) Top: the error functional $\phi' = (\mathbf{s} - \hat{\mathbf{s}})^T \mathbf{W} (\mathbf{s} - \hat{\mathbf{s}})$ with $W_{ij} = \exp(-\alpha|i - j|)$ for a minimal amount of mixing ($\alpha = 0.05$) as a function of the center frequency ω , still showing a global and a local minimum, compare with Figure 1(c). (b) Middle: similar to (a) but with $\alpha = 0.03$, the mixing is stronger and the local minimum weaker. (c) Bottom: similar to (a) but with $\alpha = 0.01$, the mixing is now strong enough to smooth out the local minimum

variable parameters are the shifts of the methyl and methylene groups, so that we see a two-dimensional surface in three-space. This eggbox-like error surface can, however, give only a rough idea of the myriad of local minima to be expected in the general case of a multidimensional error space. When we introduce the mixing matrix $\mathbf{W}$, the shape of the surface is changed as shown in Figure 3(c). Just as for the two-line case, the surface is smoothed and there is a critical value of α for which the surface exhibits one minimum only [Figure 3(d)].

One must, though, not fall into the trap of thinking that this one minimum corresponds directly to the true global minimum of the unmodified surface. That would be too easy! We could then take a strong mixing matrix $\mathbf{W}$, locate the unique minimum, replace $\mathbf{W}$ with the unit matrix $\mathbf{I}$ and find ourselves in the global minimum. Unfortunately this does not work. But what we can conceive is a gradual reduction in the mixing during which the minimum which we at first locate on ϕ' mutates into the global minimum of ϕ , and if the process is adiabatic then we can follow the change.¹¹

This is roughly the policy of DAVINS (Direct Analysis of Very Intricate NMR Spectra), but in the actual computer program a gradual change in $\mathbf{W}$ was not realized, rather the concept was followed of first locating the minimum on one surface ϕ'_0 , then reducing the degree of mixing in order to change to another surface ϕ'_1 , locating the minimum on this, then changing to ϕ'_2 , and so on. The requirement for such a scheme to be successful is that the minimum on ϕ'_n must lie within the convergence radius of the correct minimum on

Figure 3 (a) Top left: 100 MHz ^1H spectrum of the ethyl group of ethylbenzene. (b) Bottom left: a section of the corresponding error surface ϕ in three-space. (c) Top right: modified error surface ϕ' with exponential mixing $\alpha = 0.1$. (d) Bottom right: similar to (c) but with $\alpha = 0.01$. (Reproduced by permission of Academic Press from D. S. Stephenson and G. Binsch, *J. Magn. Reson.*, 1980, **37**, 395)

ϕ'_{n+1} . With this procedure, we should eventually arrive at the global minimum of the unmodified surface ϕ .

Although specific details of the matrices $\mathbf{W}$ cannot rigorously be obtained, a few general features are apparent. Firstly, in order to treat all parts of the spectrum equally, the elements should have the property that $W_{ij} = W_{i+k,j+k}$; thus $\mathbf{W}$ is a Toeplitz matrix. Secondly, the mechanism which we envisage as being responsible for the smoothing-out of local minima is equivalent to that which 'pulls' synthetic lines toward their experimental counterparts. But this is effective only if the contributions to the error arising from the off-diagonal elements of $\mathbf{W}$ are made dependent on the absolute distance between corresponding lines in such a way that ϕ' increases monotonically as a function of their separation. Thus, the elements W_{ij} should decrease monotonically as a function of their distance from the main diagonal of $\mathbf{W}$, i.e. $W_{i,i+k} > W_{i,i+k+1}$. Other restrictions on the form of $\mathbf{W}$, such as setting all the diagonal elements equal to unity, may be chosen to fulfill technical requirements, but are not essential. Within this framework the choice of suitable function is completely free, but Stephenson and Binsch found that the exponential $W_{ij} = \exp(-\alpha|i$

$-j|)$ and Lorentzian $W_{ij} = 1/(1 + \beta|i - j|^2)$ forms proved satisfactory.

6 IMPROVEMENTS TO DAVINS

The first modification to which DAVINS was subjected was the substitution of the original synthesis routines by routines allowing the inclusion of anisotropic couplings. The resulting program DANSOM¹² has been shown to be capable of analyzing spectra with thousands of transitions.¹³

The second, and more significant, modification was again the replacement of the original synthesis routines; this time by routines which took into account the full symmetry of the spin system. Whereas the original routines of Quirt and Martin¹⁴ provided for only twofold symmetry and magnetic equivalence, the routines SYMTRY and CYMTRY¹⁵ allow for symmetry in a most general form. The incorporation of these into DAVINS led to the programs DAVSYM and DAVCYM¹⁶ which are now commercially available under the name DAISY.

The most recent modification concerns a general overhaul of DAVINS undertaken by the original authors to eliminate many of its defects and to bring it up-to-date. Specifically, the areas tackled are acceleration of the calculation of the spectrum $\hat{s}$, acceleration of the calculation of the mixed error function ϕ' , and the inclusion of the ability to treat a multitude of Hamiltonians. Furthermore, the program is now furnished with an X-Windows graphical user interface, and the various modules can run on separate networked computers. The first phase of this project, leading to DAVINX, was completed in 1995.

7 APPLICATIONS

Details of the analysis of common NMR spectra using DAVINS together with recipes for successful application have already been published.¹⁷ The guidelines recorded then remain valid even today, although modified by the experience gained using the program interactively. The characterization of spectra on the basis of 'peak clustering' is still an important criterion in deciding how to approach a full automatic analysis. Consequentially, the choice of type and degree of the initial mixing is strongly dependent on the structure of the spectrum.

For clustered spectra, i.e. those in which groups of lines huddle round their respective chemical shifts, the calculation should iterate on all the parameters using initially a moderate exponential mixing. The program should be allowed to move through its repertoire of modified error surfaces until it reaches the global minimum of the unmodified surface ϕ (we christened the ensemble of these operations a 'grand cycle'⁷). It should have reached the correct solution within one grand cycle.

Spectra of this type may well be analyzed by other means, but an automatic analysis is to be preferred not only because of its ease but because the full information content of the spectrum is employed in determining the parameters. An example of such an analysis is provided by the 400 MHz ^1H spectrum of 1,2-dimethyl-3-cyanocyclopropane shown in Figure 4. The shifts are readily extracted by inspection and the few couplings are reasonably well known, but line assignments would have been difficult. An automatic analysis is a matter of a few mouse-clicks!

A significant part of our effort concerned the reduction of spectrum artifacts such as baseline anomalies, but these problems can now regularly be taken care of by standard NMR software and no longer need be part of the analysis program itself. However, since the program calculates a synthetic spectrum using a Lorentzian lineshape, it is worthwhile ensuring that the experimental lineshape also has this form—in cases of extreme deviation it is profitable to reconvolute the spectrum.¹⁸ Furthermore, a zero- and first-order correction should always be made to the baseline because the total spectral integral is one of the constraints on the iteration. Both of these forms of preprocessing were applied to the spectrum in Figure 4(a) before the analysis was started.

For spectra in which the clustering is not visible, it is advisable to start with a strong exponential mixing and iterate just on the dominant parameters in the first grand cycle; these are usually the chemical shifts, but for liquid crystal spectra comprise the major dipolar couplings. Subsequent grand cycles should employ moderate Lorentzian mixing iterating on the

Figure 4 (a) Top: 400 MHz ^1H spectrum of 1,2-dimethyl-3-cyanocyclopropane after preprocessing as described in the text. (b) Bottom: synthetic spectrum. (c) Expansion of the region 1.30–1.45 ppm of the experimental spectrum. (d) Expansion of the region 1.30–1.45 ppm of the synthetic spectrum

dominant parameters initially and then on all parameters. This, however, is no panacea, especially if the initial values are taken from the telephone book.¹⁷ In cases where only poor estimates of the parameters exist, it may be necessary to initiate several trial runs starting from combinations of values which broadly cover the expected ranges of the parameters to be varied. This grid search approach is time-consuming but will, provided the grid is chosen finely enough, lead to success.

Just such a method was adopted for the analysis of the spectrum of allyl chloride oriented in the nematogen Phase V and shown in Figure 5(a). Since the dipolar couplings could not be predicted with any accuracy, the coupling between the allylic methylene protons was estimated from the width of the spectrum and eight trial runs made with the other couplings set at ± 200 Hz with random sign combinations. Several of these runs completed their first grand cycle with significant reduction of the error function ϕ and could be

Figure 5 (a) Top: ^1H spectrum of allyl chloride oriented in Phase V after baseline correction. (b) Bottom: synthetic spectrum. (Reproduced by permission of Heyden & Son from D. S. Stephenson and G. Binsch, *Org. Magn. Reson.*, 1980, **14**, 226)

used as the basis for subsequent grand cycles iterating on all couplings and shifts. These secondary grand cycles with moderate Lorentzian mixing all yielded essentially the same parameter values, which were further refined under inclusion of the linewidth to produce the spectrum shown in Figure 5(b).

In conclusion, it may be said that with the advent of UNIX workstations as both host and satellite computers linked to NMR spectrometers, the automatic analysis of NMR spectra has come of age. Indeed, the major application might well be in the routine analysis of 'simple' NMR spectra rather than in the unraveling of spectra containing many thousands of lines.

1 INTRODUCTION

Carbon-13 nuclear magnetic resonance, ^{13}C NMR, spectrum simulation involves converting structural information into a simulated spectrum via calculation. Spectral simulation can be very useful in aiding chemists in the solution of complex structure elucidation problems and in the verification of chemical shift assignments.

This article will discuss the simulation of ^{13}C NMR spectra by empirical modeling techniques. The four most common methods of ^{13}C NMR spectral simulation involve linear additivity relationships, database retrieval techniques, quantum mechanical methods, and empirical modeling. The utility of linear additivity relationships has been studied by many researchers including Zupan et al.¹ and Fürst and Pretsch.² This technique utilizes a large database of carbon atoms and their associated chemical shifts to derive empirical parameters for a variety of structures and functionalities. The chemical shift of a new atom in a particular environment can then be calculated using the empirical parameters derived from similar atomic environments in the form of simple linear equations. Although this approach can be applied to a wide range of compounds, standard errors in excess of 5 ppm are common.

Database retrieval techniques^{3,4} also rely on access to a large database containing carbon atoms and their corresponding known chemical shifts. To simulate the ^{13}C NMR spectrum for a query compound, the most similar atomic match is found from the database for each unique atom in the query. The chemical shift associated with each matched database atom is retrieved as the predicted chemical shift for each atom in the query. This method is applicable to a wide variety of compounds, but its accuracy is highly dependent on the size and breadth of the database and the nature of the similarity metric used for carbon atom retrieval.

Quantum mechanical methods for ^{13}C NMR spectral simulation involve the use of molecular orbital theory calculations such as INDO and MINDO/2.^{5,6} Chemical shielding is calculated in two parts: diamagnetic shielding (created by the induced current around the nucleus of interest)

and paramagnetic shielding (the degree to which the specific chemical environment quenches the induced current around the nucleus). Recent work by Baker and Zerner⁶ reports the calculation of ^{13}C NMR shifts using an intermediate neglect of the differential overlap model for several relatively small hydrocarbons and other simple molecules. Quantum mechanical methods typically require extensive computational time and are applied only to relatively simple molecules.

Empirical modeling techniques involve the development of mathematical models from a dataset of known chemical shifts. These models relate the chemical shift of an atom to various atom-based structural parameters (descriptors). When such a model is derived using multiple linear regression, it may have the following form:

$$S = b_0 + b_1X_1 + b_2X_2 + \dots + b_nX_n \quad (1)$$

where S is the chemical shift of an individual carbon atom, the X_i quantities are the descriptor values, and the b_i quantities are coefficients determined by multiple linear regression analysis. Computational neural networks can also be used to develop models which relate descriptors to chemical shifts. Once the model is developed, it can be utilized to predict the chemical shifts for carbons not contained in the original dataset. A limitation of this technique arises because the model equations can only be used to predict the shifts for atoms that are structurally similar to those used to develop the models. Unlike database retrieval techniques however, these models have the ability to interpolate chemical shifts. In addition, this technique typically yields simulated spectra with standard errors on the order of 1.0 ppm. This article will focus on the methodology involved in developing empirical models for ^{13}C NMR spectral simulation and present an extended example of application of the method to tetrahydropyran compounds.

2 METHODOLOGY FOR THE DEVELOPMENT OF INDIVIDUAL MODELS

The methodology used to develop mathematical models for ^{13}C NMR simulation is illustrated in Figure 1, and each step will be described in the following discussion.

2.1 Selecting a Dataset

The first step involved in a ^{13}C NMR spectral simulation study is determining the class of compounds to be studied. Once a set of compounds is selected, their corresponding ^{13}C NMR spectra are obtained from the primary literature or data compilations. One such compilation of ^{13}C NMR data is that of Chemical Concepts GmbH, which currently contains 68 207 compounds ($\text{C}_1\text{--C}_{86}$) with 83 591 associated spectra. After chemical shifts are assembled into spectra, they should be checked against the primary literature to minimize the probability of errors. Typically, 90% of the carbon atoms and their associated shifts are used as the training set (a set used to generate the model equations), and the remaining 10% are set aside as a prediction set (a set used to test the external predictive ability of the model equations after model development is complete).

Figure 1 Flow chart of ^{13}C NMR simulation study

2.2 Structure Entry and Modeling

The molecular structures are entered as two-dimensional sketches and stored as connection tables in a database. In addition to the molecular structures, the ^{13}C NMR spectrum for each compound is stored. The two-dimensional representations of the compounds are then submitted to molecular modeling to generate three-dimensional molecular models. A simple, interactive classical molecular mechanics routine is used as a starting point.⁷ The models are then refined using the molecular mechanics approach of MM2.⁸ Some bond types and atomic arrangements cannot be modeled by MM2, in which case it is necessary to use molecular orbital methods such as MOPAC.⁹ Three-dimensional representations of the structures are necessary for subsequent computation of geometrical descriptors. Such geometric descriptors are

essential to ^{13}C NMR simulation because shift values are highly dependent on geometric relationships in the structures.

2.3 Unique Atom Perception

It is important to include only the unique atoms (those in structurally unique surroundings) in the dataset when generating models. Unique atoms give rise to unique chemical shifts. If an atom and its corresponding chemical shift are represented more than once in the dataset, then the models can become unduly skewed or biased to account for that particular atom type.

2.4 Atom Subsetting

The carbon atoms in a set of compounds are usually structurally diverse, so it may be difficult to generate one model capable of simulating accurate ^{13}C NMR shifts for all the atoms together. In such cases, the dataset can be divided into smaller, more homogenous sets of atoms. In many studies, subsetting has been primarily based on carbon atom connectivity (1° , 2° , 3° , 4°), or position relative to a functional group (e.g., the number of bonds distant from a carbonyl group). Model equations are then developed independently for each atom subset. Whenever possible, subsetting is not employed and one overall model is generated for all carbon atoms in the set of compounds. The flow chart of Figure 1 does not include subsetting of the data because it is only done when necessary.

2.5 Descriptor Generation

Once the unique carbon atoms have been identified and stored, the structural environment surrounding each carbon atom must be encoded. The chemical environments are represented by numerically encoding the topological, electronic, and geometrical features that surround each carbon atom, as illustrated in Figure 2.

These calculated numerical representations of the chemical environments are called descriptors. Since the chemical shift of a carbon atom is not significantly affected by the chemical environment more than five bonds away, descriptors are only computed based on structural features located one to five bonds distant from the carbon center of interest. More than 700 atom-based descriptors have been implemented in ^{13}C NMR spectral simulation studies. A few examples of the topological, electronic, and geometrical descriptors that have been found to be important in numerous studies are described here. A complete list of the atom-based descriptors that can be calculated has been presented elsewhere.¹⁰

Topological Descriptors: The simplest descriptors are topological and are calculated directly from the connection table representations of the structures. These descriptors include atom counts, valency counts, and molecular connectivity indices. Molecular connectivity indices are graph theoretical descriptors derived from the topological representation of molecular structures, and they encode size, shape, and branching information.¹¹ The most commonly used atom count descriptor is the number of carbon atoms located three bonds

Figure 2 Schematic diagram of atom-based descriptor generation

from the carbon center of interest. This descriptor appeared in five of the first 66 regression models in the library of models for ^{13}C NMR simulation. The most widely used valency count descriptor encodes the number of tertiary carbons that are located one bond from the carbon center of interest. This descriptor has appeared in 10 of the first 66 regression models in the library. Connectivity indices encode the degree of branching that surrounds a given carbon atom. The average connectivity index over the carbon atoms one bond from the carbon center has been the most useful descriptor in this category, appearing in four of the first 66 regression models.

Electronic Descriptors: The electronic properties of the portion of the structure near a given carbon atom are computed by first calculating the partial atomic charges for each heavy atom (nonhydrogen) in the compound. These partial atomic charges are computed using extended Hückel,¹² Del Re,¹³ or an empirical method recently reported¹⁴ based on an extension of work by Abraham and Smith.¹⁵ Once these partial charges have been computed, the total atomic charge, the average atomic charge, the most negative atomic charge, and the most positive atom charge are calculated from one to five bonds from the carbon center being described. All three of the partial atomic charge calculation methods have been quite useful, but the most widely used electronic descriptor is based on Del Re methods and computes the sum of the σ charges on all heavy atoms located three bonds from the carbon center of interest. This descriptor has been used in six of the first 66 regression models in the library.

Geometrical Descriptors: The most sophisticated descriptors are geometrical in nature and are dependent on the three-dimensional coordinates obtained from molecular mechanics. Because these descriptors are dependent on calculated geometries, they possess an added degree of experimental uncertainty. Examples of geometrical descriptors include through-space distance calculations and shell counts, illustrated in Figure 3.

As shown, one through-space descriptor encodes the sum of inverse cubed through-space distances from the carbon center (here a carbonyl carbon) to all primary carbons located two bonds away. An example of a shell count descriptor

Figure 3 Diagram showing through-space distances and shell counts used for descriptor generation

would be to count the number of hydrogens that are located in the spherical shell from 3.6 Å to 5.0 Å from the carbon center. The radii of the shells used were found by systematic investigation of simple compounds for distances that were most representative of structural classes. The most commonly used geometrical descriptor (present in 20 of the first 66 regression models), however, is a van der Waals energy descriptor.¹⁶ This descriptor calculates the van der Waals energy of the carbon center interacting with all hydrogen atoms in the molecule.

2.6 Descriptor Screening

In order to assure their statistical significance, the descriptors are screened before being submitted to multiple linear regression analysis. Only information-rich descriptors pass the screening step for further analysis. This step is performed independently for each atom subset since a particular descriptor may contain useful information for one subset but not for another. Descriptors are generally removed from consideration if they contain mostly identical or zero values for the entire atom subset, or if they are highly correlated with other descriptors. The overall goal of descriptor screening is to reduce the size of the data matrix (minimize the number of descriptors used) while retaining the maximum amount of information.

2.7 Model Development by Regression

The descriptors that survive screening are submitted to multiple linear regression analysis. Forward selection,¹⁷ backward deletion,¹⁷ and leaps-and-bounds regression¹⁸ are among the methods used to select descriptors and develop final models. Leaps-and-bounds regression is an automated technique that simulates performing all possible regressions by considering optimal subsets of descriptors. The objective is to find the best mathematical model that relates the chemical shifts of the carbon atoms comprising the training set to their experimental ¹³C NMR shifts using the smallest number of descriptors of those available. Typically, there should be at least five chemical shifts for each descriptor present in a model. If the problem under investigation involves several subsets, a separate model is developed for each atom subset. After the models are developed, the simulated spectra can be assembled from the individual chemical shift predictions.

2.8 Model Evaluation

Various methods are utilized to validate each model. Models with high multiple correlation coefficients, R , and low standard errors of regression, s , are desirable. The goal is to find models with s values less than 1.0 ppm. Plots of calculated versus observed chemical shifts and residual error versus calculated shifts can be used to test visually for outliers, nonconstant variance, and other statistical problems.¹⁹ Each model is also internally validated using jackknifing. This involves regenerating the model coefficients for the training set with one chemical shift removed, and then predicting the value for the removed carbon atom. This is done once for each chemical shift in the training set, and the averaged results obtained are indicative of the quality of the model. Another important model evaluation step is external prediction. Using an external prediction set, the models are used to predict the shifts for atoms which were not included in the original training set.

2.9 Spectral Assembly and Evaluation

Once the individual chemical shifts have been calculated for all of the carbon atoms in the training and prediction sets, they are combined to form simulated ¹³C NMR spectra for entire compounds. Once assembled, the root mean square (rms) errors between simulated and observed spectra are calculated. Generation of simulated spectra that have rms spectral errors of 1.0 ppm or less is the goal. If the rms spectral errors produced by a model are unacceptable, then new models are generated or subsetting of the data may be tried.

Another technique used to evaluate the quality of the simulated spectra is library searching. Library searching involves comparing a simulated spectrum for a compound against a library of over 1000 stored spectra which contains the observed spectrum for the same compound. If a simulated spectrum is of high quality, then the most similar spectrum (the spectrum retrieved as the top match) should be the observed spectrum of the same compound or a very similar one. The goal is to generate simulated spectra which are accurate enough to retrieve their observed spectra as number one matches in all cases. It has been observed that this is possible when rms spectral errors of 1.0 ppm or below are obtained.

2.10 Adding Models to the Library

Once suitable regression models have been developed and have passed the spectral assembly and evaluation steps, they are stored in the regression model library for future use in automated ¹³C NMR spectral predictions. Within the regression model library, there are four databases which contain information about all the molecular structures, carbon atoms, regression models, and atom-based descriptors that were used to build the library. The information in these databases is essential for performing automated spectral predictions and must be updated as new models are checked in.

The *structure database* identifies every compound that was used in the development of a regression model. In addition, the energy-minimized three-dimensional coordinates are stored for each of these compounds. The *atom database* contains information about each unique carbon atom that was previously used to develop a regression model. Each carbon atom in this database possesses a unique index number and its observed chemical shift is also stored. The *model database* contains information about each regression model including the statistics associated with each model, the intercept, the regression coefficients, and the descriptor index associated with each coefficient. The *descriptor database* contains the unique indices associated with the 718 descriptors that can be calculated. In addition, this database indicates which ADAPT programs must be executed to compute each descriptor and the necessary settings that must be utilized. This information is necessary during predictions of spectra for unknown compounds.

3 REGRESSION MODEL LIBRARY

The long-term goal of such a system is to develop the capability to simulate accurate ¹³C NMR spectra for a wide variety of organic compounds directly from their structures in an automated fashion. In order to pursue this goal, a library containing previously developed regression models (predictive equations) was constructed.

In the past, the primary focus was the development of empirical models for limited sets of structurally homogeneous compounds. However, more recently, the utility of combining database retrieval and empirical modeling techniques has been investigated in an attempt to benefit from the advantages offered by both techniques. In this combined approach, predictive equations are retrieved from a library of stored regression models to calculate the chemical shifts for each atom in a query compound. For this approach to be successful, two tasks must be accomplished. First, the library of predictive regression equations must be broadly applicable, i.e. models capable of simulating accurate shifts for many different atomic environments must be developed and stored. Second, an effective algorithm capable of selecting the most appropriate model to use for predicting the shift of a query atom needs to be developed.

A total of 87 regression models capable of simulating ¹³C NMR spectra for a variety of structural classes has been developed and stored in a library of regression

equations. The structural classes represented are as follows: linear and branched alkanes,²⁰ cycloalkanes,²¹ cyclohexanols and decalols,²² hydroxysteroids,²³ cyclopentanes and cyclopentanols,²⁴ norbornanols,²⁵ cyclohexanones and decalones,²⁶ piperidines,²⁷ polychlorinated biphenyls,²⁸ alkyl-substituted benzenes and polyaromatics,²⁹ keto-steroids,³⁰ quinolines and isoquinolines,³¹ cyclopentanones and cycloheptanones,³² side-chain atoms on ring systems,³³ indoles,³⁴ hydroaromatics,³³ polysaccharides,³⁵ and tetrahydropyrans.³⁶ These models are listed in Table 1.

As shown in Table 1, three to eight models have been developed for each compound class except for polysaccharides and tetrahydropyrans where only one model was necessary. Each model was developed for a subset of the carbon atoms found in the compounds being studied and the number of atoms used in the development of each model are shown in parentheses after the identity of each model. More than 6000 carbons were used to develop the set of 87 models. Models 8, 12, and 63 were each developed with fewer than eight observations. Because fewer than eight observations were not sufficient to generate statistically valid regression models, the average chemical shift of each atom subset was used in place of traditional regression equations. Each compound class was studied independently and the standard set of procedures described above were followed in order to develop the regression models.

4 MODEL SELECTION

To use the models for predicting the shifts of unknowns, an effective procedure for choosing the best model from the library must be available. A flow chart of this selection process is shown in Figure 4.

Currently, a nearest neighbor approach to model selection is being utilized. The development of this approach has been described.¹⁷ The current model library contains the 87 predictive equations shown in Table 1. The atomic environment surrounding each of these atoms is encoded using a set of seven topological descriptors. These seven descriptors include the six EVEC descriptors³⁷ used in the original model selection procedure³⁸ and Randić's atomic ID descriptor.³⁹ As a set, these seven variables provide sufficient information about the surroundings of each carbon atom to make selection from the library possible.

To select a model for the prediction of a query atom in an unknown, the following procedure is followed. The seven descriptors are calculated for the query atom. In order to find the most similar atomic match, the Euclidean distance, d , between the query atom and each of the 5155 atoms in the database is calculated using equation (2):

$$d = [(D_1 - Q_1)^2 + (D_2 - Q_2)^2 + \dots + (D_7 - Q_7)^2]^{1/2} \quad (2)$$

where the D_i terms are the descriptor values for an individual database atom and the Q_i terms are the descriptor values for the query atom. The database atom associated with the smallest Euclidean distance is defined as the nearest neighbor atom. In a database retrieval scheme, the shift associated with this nearest neighbor atom would be assigned to the query atom. In our scheme, the model developed from the nearest neighbor atom

Figure 4 Flow chart of ^{13}C NMR shift prediction using model library

is used to calculate the chemical shift for the query atom. To do this, the descriptors that were used in the selected model are computed for the query atom. Then, these descriptor values are multiplied by the appropriate coefficients and the chemical shift is predicted. This entire procedure is repeated for each atom in the query compound until the complete ^{13}C NMR spectrum is simulated.

An illustration of this method was developed when the model library contained the first 71 models. The spectrum for 2,2,5-trimethylcyclopentanone was simulated. This compound was not used to develop any models in the database but is similar to the compounds used in the cyclopentanone and cycloheptanone study. The molecular structure, observed ^{13}C NMR spectrum, and simulated ^{13}C NMR spectrum are shown in Figure 5.

For each of the seven carbon atoms in the query compound, an appropriate model was selected from the model library. The figure visually illustrates the high degree of similarity between the simulated and observed spectra. The standard error of estimate for this simulated spectrum was 0.81 ppm. It should be emphasized that this entire procedure is fully automated, and it took less than 4 min to generate a complete simulated spectrum starting from the energy-minimized three-dimensional molecular structure.

This automated model selection procedure can be used to probe the regression model library systematically to determine if any weaknesses are present. A weakness in the library means that the ^{13}C NMR spectra for a class of compounds cannot be simulated with the desired accuracy. When such deficiencies are identified, models which address them can be developed. Two independent studies were recently performed which probed the model library and identified two such weaknesses. The first study involved a set of cyclic compounds

6 CARBON-13 SPECTRAL SIMULATION

Table 1 List of Regression Models Forming the Library and Numbers of Carbons used to Develop Each Model

Model No.	Model description		
		48	Carbons one bond from a nitrogen (62)
		49	Carbons two bonds from a nitrogen (65)
		50	Carbons > two bonds from a nitrogen (55)
	<i>Linear/branched alkanes</i>

containing various side chains, and the second involved a set of hydroaromatic compounds. Models were developed for these classes of compounds and they were added to the library, forming models 72–75 for side chains³³ and 82–85 for hydroaromatic compounds.³³ Other recent additions to the library include models developed with sets of indoles,³⁴ polysaccharides,³⁵ and tetrahydropyrans.³⁶

5 NEURAL NETWORK PREDICTION OF ¹³C NMR SPECTRA

The models discussed up to this point were developed via multiple linear regression analysis and they had the form of equation (1). Such models assume a linear relationship between the individual carbon atom descriptors and the chemical shifts. It is possible to use transformations of individual descriptors to introduce nonlinearities, but this must be done in an ad hoc manner. As seen, the approach with linear models has been successfully used to develop models for many classes of compounds. However, nonlinear relationships between the descriptors and chemical shifts are undoubtedly present, and methods to take advantage of this information should lead to superior simulation ability. The use of computational neural networks provides such an opportunity to utilize nonlinear relationships.

A computational neural network is an assembly of simple units, called neurons, organized in a highly-connected array.^{40,41} Three types of neurons comprise a network: *input* neurons which accept the input data characterizing each observation; *output* neurons which provide the predicted value or pattern; and *hidden* neurons connected to the input or output

neurons to provide intermediate processing. A fully-connected, feed-forward neural network consists of these three types of neurons arranged in layers with connections linking each neuron in a given layer and all of the neurons in the succeeding layer (Figure 6).

For simplicity, the network shown has just one output neuron which would provide a quantitative value for the predicted chemical shift. The network functions by receiving a set of input values, processing them, and then producing an output value calculated from these input values. A network is trained through repeated presentations of input and target pairs. The adjustable weights associated with the links within the network are systematically altered during training to reduce the error, and their values constitute the memory of the network.

The most widely used training algorithm is called back-propagation because the errors in the outputs are propagated backward through the network to systematically alter the weights. Back-propagation is a gradient descent method. The objective of training a network is to create a system that can properly reproduce all of the target values given the set of input values. Neural networks often have a large number of adjustable parameters (the weights) and they can be prone to overtraining. This occurs when training continues through too many iterations and the network focuses on learning the individual idiosyncrasies of the training set patterns which diminishes its ability to predict for unknowns. Overtraining is avoided by using a cross-validation set of patterns to test the network periodically during training, and terminating training when the cross-validation set error is minimized. After training is complete, the network can then be used to predict the outputs for a new set of inputs.

Recently, there has been a great deal of interest in neural networks in many areas of science and technology including engineering, biology, and the cognitive sciences.⁴² Neural networks have been applied to several areas of chemistry,⁴³ including ¹H NMR spectroscopy^{44,45} and ¹³C NMR spectroscopy.⁴⁶ A review article covering many applications of neural networks in analytical chemistry has appeared,⁴⁷ and a tutorial was recently published.⁴⁸

Several studies have been undertaken in which back-propagation neural networks were used as a supplement to regression analysis to link the atomic structural environment descriptors to the ¹³C NMR shifts.^{35,36,49} Neural networks have also been used for the task of choosing models from the regression model library for use in predicting the ¹³C NMR spectrum of a query compound.⁵⁰ Excellent results have been achieved, which lead us to believe that expanded use of neural networks for the prediction of ¹³C NMR spectral shifts will follow.

Recently an advanced quasi-Newton neural network training algorithm called BFGS (Broyden–Fletcher–Goldfarb–Shanno)⁵¹ was reported. This method computes the step size for the correction for each weight during the computation, yielding quicker convergence. It provides a superior performance to the standard back-propagation method, both in terms of speed of training and final results, and it was applied to ¹³C NMR simulation.^{35,36}

6 ¹³C NMR SIMULATION OF PYRANS

As an example of the capabilities of this ¹³C NMR simulation approach, a recent study of tetrahydropyrans³⁶ is

Figure 6 Architecture and function of a fully-connected, feed-forward computational neural network

described. The ^{13}C NMR spectra of the tetrahydropyrans were simulated directly from their molecular structures using the methodology described above. A set of 29 tetrahydropyrans was used as a training set to generate regression equations and to train neural networks, and three additional compounds were used as a cross-validation set. The results of simulations undertaken by regression analysis were found to be extremely sensitive to molecular geometries. To account for this, two different methods of descriptor manipulation, an averaging method and a Boltzmann-weighted averaging method, were developed, and the models generated from the descriptor sets were compared. The results for the Boltzmann-weighted averaging method were found to be superior to those based on descriptors derived from only the lowest energy molecular conformations.

The 32 tetrahydropyran compounds and ^{13}C NMR spectra used for this study were obtained from the Chemical Concepts database (Weinheim, Germany) and are listed in Table 2. Compounds 1–29 were used as a training set, and 30–32 were used as a cross-validation set to test the external predictive ability of the equations generated by regression analysis. The three compounds in the cross-validation set were chosen randomly. The experimentally observed shifts fall into two groups: the atoms not bonded directly to an oxygen (shifts ranging from 5.07 ppm to 46.06 ppm), and the atoms bonded directly to an oxygen (shifts ranging from 63.43 ppm to 80.21 ppm). All the carbons were treated as one dataset, and it was not necessary to divide them into subsets in this study.

Each compound was modeled with molecular mechanics using MM2 to find the lowest strain energy conformation. Then the unique carbon atoms from each compound were identified. The training set is comprised of the 182 unique carbon atoms of compounds 1–29 and the cross-validation set is comprised of the 19 unique carbon atoms of compounds

^aDescriptor definition ('heavy atom' denotes all nonhydrogen atoms). MPCG 1, the most positive σ -charge among heavy atoms one bond away from the carbon center, HHI3 2, the sum of the inverse cubed through-space distance from the hydrogens attached to the carbon center to other hydrogens four bonds away; CHVD 1, the van der Waals energy due to interactions between the carbon center and hydrogens in the molecule; CHCG 1, the extended Hückel charge on the carbon center; COET 1, the van der Waals energy between the carbon center and all oxygens two or more bonds away; TOTB 1, the sum of the strain associated with torsional angles involving oxygen atoms and the carbon center in torsional bonds; MNAC 3, the most negative charge due to all heavy atoms three bonds from the carbon center; CXVD 1, the van der Waals energy due to the interactions between the carbon center and other heavy atoms; STAS 1, the smallest strain associated with a torsional angle involving the carbon center; STBS 1, the smallest strain associated with a torsional bond involving the carbon center.

^bSD = standard deviation.

^cMean effect = average shielding and deshielding contribution of each descriptor on the predicted chemical shift.

30–32. Descriptors were then generated for the 201 unique carbon atoms and screened to eliminate those with little information content, leaving 65 descriptors.

The remaining descriptors were analyzed using leaps-and-bounds regression and a nine-descriptor equation was found to yield the best results. The standard error for this model was 1.37 ppm, somewhat higher than the 1.00 ppm that is typically desired in order to generate quality spectra. The 19 carbon atoms of the cross-validation set were predicted with a standard error of 2.49 ppm. This value is larger than desirable and it has been adversely influenced by several substantial outliers.

One measure of the quality of the simulated spectra is to use the spectra as queries for library searching. When this was done against a large library, the spectra generated by this model were accurate enough that number one matches were found for all compounds. That is, the authentic spectra were retrieved as best matches to the query spectra. However, the scores, which are a measure of the quality of the spectra, were poor. The presence of several geometrical descriptors in the model indicates that the geometry of the molecule is an important determinant of the chemical shift for these tetrahydropyrans. This led to testing of the sensitivity of this model to the different conformations that tetrahydropyrans can assume.

To perform the test for the tetrahydropyrans, the lowest strain energy conformations of the molecules were regenerated in their ring-flipped, or high strain energy, conformations. Once these conformations were available, the descriptors that appeared in the best regression equation were recalculated for these conformations. These new descriptor values were then used with the regression equation and the previous coefficients. If the descriptor values were similar for both conformations, the results of the predictions would be similar. In fact, there was a large difference in the results obtained when using the descriptors derived from the two conformations. The low strain energy compounds had an rms spectral error of 1.30 ppm,

while the high strain energy compounds had an rms spectral error of 3.77 ppm. This shows that the descriptor values and the regression models derived from them produce shift predictions that are very sensitive to conformational changes. Several methods were developed in an attempt to encode other conformations in order to improve results, and a Boltzmann-weighted averaging method was found to perform the best.

To create descriptors that were averaged for the two conformations, geometric and electronic descriptors were calculated for both energy conformations, and these values were averaged using a Boltzmann weighting scheme. Using leaps-and-bounds regression, a successful 10-descriptor model was found. This model is shown in Table 3 along with its statistics. Of these 10 variables, HHI3, CHVD, CXVD, STAS, STBS, TOTB, and COET are geometrical descriptors, showing the importance of conformational information. This regression model has a standard error of 1.53 ppm.

Once regression analysis had been performed and the best descriptors for the dataset had been determined, neural networks were trained using the same data. The quasi-Newton training method was utilized to develop the networks. For the Boltzmann-weighted average conformation dataset, a neural network with the architecture 10–5–1 (five hidden layer neurons) was found to be optimum. The descriptors were presented to the networks in two groups; a training set (182 carbons) and a cross-validation set (19 carbons). Instead of determining the external predictive ability of the model, the cross-validation set was used to help eliminate the problem of overfitting the data. When the rms error for the cross-validation set fails to improve, the network is no longer giving results that are applicable to atoms not found in the dataset, and the training is stopped.

The results obtained with the Boltzmann-weighted averaging method improved dramatically compared with the regression analysis results. The error decreased from 1.53 ppm for

Figure 7 Plot of simulated versus ^{13}C NMR shifts for tetrahydropyrans

regression to an rms error of 0.74 ppm with the neural network. The neural network was able to utilize the information provided by the Boltzmann-weighted averaging method. In addition, nonlinear relationships linking the descriptors to the ^{13}C NMR shifts are accounted for by the neural network. A plot of the predicted versus observed shifts is shown in Figure 7. All of the shifts of the cross-validation set are predicted well, with a lone exception.

An example of the accuracy of the neural network model is shown by the comparison of an entire predicted spectrum to an observed spectrum in Figure 8.

This is compound 32 listed in Table 2, i.e. 2-ethyltetrahydropyran, one of the cross-validation set members. The Boltzmann-weighted averaged descriptors along with a neural network model gives a predicted spectrum that is almost identical to the observed spectrum with an rms error of only 0.68 ppm. The visual similarity between the simulated and observed spectra is striking. Furthermore, just one model has been used for all the carbons in the compound.

Thus, multiple linear regression analysis and quasi-Newton neural networks were used to predict accurately the chemical shifts of tetrahydropyrans. Descriptors based on several conformations of each molecule were shown to be more effective in these simulation studies than descriptors calculated only from low strain energy conformations.

7 SUMMARY

The methodology exists to develop models that directly link calculated structural descriptors for individual carbon atoms with their ^{13}C NMR chemical shifts. Models are developed from sets of compounds with known chemical shifts and then these models have the ability to predict the chemical shifts for new compounds. The descriptors for the carbon atoms are topological, geometrical, or electronic in nature, and they encode the surroundings of the carbons sufficiently for model development. The models can be developed using

Figure 8 Simulated and observed spectra for 2-ethyltetrahydropyran

multiple linear regression analysis or using computational neural networks. Models with rms spectral errors in the neighborhood of 1.0 ppm have been developed for a wide variety of compound classes and the models have been incorporated into a library. Current work is focusing on the simulation of the ^{13}C NMR spectra of carbohydrates directly from their structures.

1 INTRODUCTION

Nuclear magnetic shielding is a second-order molecular electronic property which provides a severe test of the accuracy of molecular quantum mechanical calculations. While electric dipole polarizability and hyperpolarizabilities provide tests of the wavefunction at the outer regions, nuclear shielding is very sensitive, especially to contributions from high angular momentum functions, in the regions close to a particular nucleus. Precise measurements of differences in shielding are easy to carry out. In most NMR studies the resonance frequencies are measured and a chemical shift is defined as $\delta = (\nu_i - \nu_{\text{ref}})/\nu_{\text{ref}}$. From the relationship between the resonance frequency ν_i , the external magnetic field B_0 , the magnetogyric ratio γ , and the nuclear shielding σ_i , i.e. $\nu_i = (\gamma/2\pi)(1 - \sigma_i)B_0$, we can write the chemical shifts in terms of the nuclear shielding as $\delta = (\sigma_{\text{ref}} - \sigma_i)/(1 - \sigma_{\text{ref}})$.

Reasonably accurate calculations are now available for nuclei in the first row of the Periodic Table in molecules with a small number of first row atoms and for hydrides of the second row, as may be seen in the articles on IGLO, LORG and SOLO and GIAO shielding calculations described by Kutzelnigg, Hansen and Pulay in this Encyclopedia (*Shielding Calculations: LORG and SOLO Approaches, Shielding Calculations: IGLO Method, Shielding Theory: GIAO Method*). In making a comparison of theoretical ab initio values at the equilibrium molecular geometries with experimental chemical shifts, it is necessary to have absolute quantities (absolute shielding values) to compare with rather than shielding differences or chemical shift values. Accurate chemical shift measurements can be carried out by simultaneous measurement of two frequencies in the same physical sample in the field. If we know the absolute shielding value corresponding to the first frequency, then the accurate chemical shift between the two provides the absolute shielding of the second, or indeed of any number of systems whose chemical shifts can be related to the absolute shielding of any

one system. But how do we establish the absolute shielding value of the very first one?

2 ABSOLUTE SHIELDING SCALES BASED ON THE PROTON IN LIQUID WATER

The absolute proton shielding in a spherical sample of pure liquid H_2O at 34.7°C , $\sigma = 25.790 \pm 0.014$ ppm, has been established by two experiments. The first was a simultaneous measurement of the frequencies of an electronic transition and a nuclear magnetic transition in atomic hydrogen. The second was a simultaneous measurement of NMR frequencies of protons in a spherical sample of liquid water at 34.7°C and in a spherical bulb filled with atomic hydrogen in the same magnetic field. The first experiment established the g -factor of the bare proton; the second experiment allows the determination of the absolute nuclear magnetic shielding of protons in liquid water.^{1,2}

One standard technique for establishing an absolute shielding scale for a nucleus M is by combining the results of two experiments. The first is an atomic beam magnetic resonance experiment or an optical pumping experiment which measures the ratio of γ for the M nucleus to γ for the electron in the free M atom. Since the (electron) γ can be calculated from the known electron magnetic moment and electronic g -value of the atomic state, the value of $\gamma(M, \text{free atom})$ may be obtained precisely. The second is an NMR experiment which measures the ratio of the Larmor frequencies of M and ^1H in an infinitely dilute $M_{(\text{aq})}^{n+}$ ion in aqueous solution. This provides the ratio $\gamma(^1\text{H}, \text{H}_2\text{O}, \text{liq.})/\gamma(M, M_{(\text{aq})}^{n+})$. The key here is that $\gamma(^1\text{H}, \text{H}_2\text{O}, \text{liq.})$ is known precisely for pure liquid water from experiments and is assumed to be the same in the infinitely dilute aqueous solution of $M_{(\text{aq})}^{n+}$ ion, so $\gamma(M, M_{(\text{aq})}^{n+})$ can be obtained. Then, from the definition of the nuclear magnetic shielding σ relative to the bare nucleus, $\gamma = (1 - \sigma)\gamma_0$, where γ_0 is the magnetogyric ratio of the bare nucleus,

$$\frac{\sigma(M, \text{free atom}) - \sigma(M, M_{\text{aq}}^{n+})}{1 - \sigma(M, M_{\text{q}}^{n+})} = 1 - \frac{\gamma(M, \text{free atom})}{\gamma(M, M_{\text{aq}}^{n+})} \quad (1)$$

Since $\sigma(M, \text{free atom})$ is theoretically known³ the absolute shielding of M in the aqueous solution of $M_{(\text{aq})}^{n+}$ is thereby established.

This method is applicable when the aqueous solution of the metal ion is a convenient reference and extrapolation to infinite dilution is possible. The ratio $\gamma(M, \text{free atom})/\gamma(M, \text{liq. ref.})$ has to be known to 1 part in 10^5 if the $\sigma(M, \text{liq. ref.}) - \sigma(M, \text{free atom})$ is to be determined to ± 10 ppm. The absolute shielding scales for Li, Na, K, Rb, Cs, Zn, Cd, Ga, Hg, and Pb were determined in this way and are summarized in Table 1 in 'Multinuclear NMR' edited by Mason.⁴

3 ABSOLUTE SHIELDING INFORMATION FROM SPIN-ROTATION CONSTANTS

With the gauge origin at the nucleus in question, σ^{P} in Ramsey's expression is related to another molecular property,

Table 1 Absolute σ_0 ^{15}N Shieldings

Molecule	$\sigma_0(^{15}\text{N}$ in the molecule, 300 K) (ppm)
N_2	-61.6
NNO	99.5
NNO	11.3
HCN	-20.4

the nuclear spin-rotation tensor. The nuclear spin-rotation tensor arises from the coupling of the magnetic moment of a nucleus with the magnetic field generated by the molecular rotation at that nucleus. Ramsey⁵ and Flygare⁶ have shown that

$$\sigma_{\text{gg}}^{\text{p}} = (m_{\text{p}}/2m g_N) C_{\text{gg}}/B_{\text{gg}}^{(\text{e})} - (\mu_0/4\pi)(e^2/2m) \times \sum_N Z_{N'} [R_{NN'}^2 - (R_{NN'}^2)_{\text{gg}}]/R_{NN'}^3 \quad (2)$$

in which m_{p} and m are the masses of the proton and the electron, g_N is the g -factor for the nucleus of interest, C_{gg} and $\sigma_{\text{gg}}^{\text{p}}$ are the diagonal components of the spin-rotation tensor and the paramagnetic shielding tensor in the principal axis system of the molecular moment of inertia, while $B_{\text{gg}}^{(\text{e})}$ is the rotational constant at the equilibrium configuration.

The $\sigma_{\text{gg}}^{\text{p}}$ values can be related to the components along the principal axes of the shielding tensor by a rotational transformation using the known molecular geometry. The second term in the equation is the nuclear contribution which depends only on the coordinates and atomic number of all the other nuclei N' in the molecule. The total absolute shielding can then be determined by adding the diamagnetic contribution σ^{d} , which is obtained from theory, calculated at the nucleus of interest N as the gauge origin:

$$\sigma^{\text{d}} = (\mu_0/4\pi)(e^2/3m) \left\langle \psi^0 \left| \sum 1/r_i \right| \psi^0 \right\rangle \quad (3)$$

It is very important to calculate the nuclear terms using the same structure as that used for calculating diamagnetic terms.

Experimental values of spin-rotation constants are available from molecular beam magnetic and electric resonance experiments and also from high-resolution microwave spectroscopy. In the first two types of experiments the radiofrequency spectrum corresponding to the reorientation of the ^{15}N nuclear moment in a magnetic field, or the interaction of the electric dipole moment of the molecule with a strong external electric field, is composed of transitions from many J and M_J states which may be individually resolved. In the third type of experiment, a specific purely rotational transition is observed. Vibrationally averaged constants are obtained, usually for the ground vibrational state, occasionally for a vibrationally excited state as well. The exact relation between σ^{p} and C holds for a vibrationless molecule at the equilibrium nuclear configuration. Experimentally one usually obtains $\langle C \rangle_{v=0}$ components of the vibrationally averaged spin-rotation constant.

The first absolute shielding scale which was compiled in an internally consistent way is the one for ^{19}F in a small set of molecules whose chemical shifts have been measured in the limit of zero pressure at room temperature.⁶ To establish the first absolute shielding for ^{19}F in a molecule,⁷ Hindermann and

Cornwell corrected the observed spin-rotation constant in HF to the equilibrium configuration, from which they obtained σ_e^{p} . The latter combined with the theoretical value of σ_e^{d} gave σ_e , which was then converted to σ_0 at room temperature by making the rovibrational correction. Once the absolute σ_0 for HF was known, they could then find the absolute σ_0 for their secondary reference molecule (SiF_4) by measuring the chemical shift between HF and SiF_4 at the zero-pressure limit. The absolute σ_0 for the other molecules on their scale were then determined from measured chemical shifts from SiF_4 . Since all the measured chemical shifts correspond to the zero-pressure limit, Hindermann and Cornwell's scale is a list of absolute σ_0 (i.e., for the isolated molecule) at room temperature. In addition, they found the absolute shielding $\sigma(\text{liq.}, T)$ of CFCl_3 . With this connection, other measurements of shifts relative to liquid CFCl_3 can be converted to absolute $\sigma(\text{liq. or soln.}, T)$ by other workers.

In general, once the absolute shielding of a primary reference molecule (in this case the HF molecule) has been established, the absolute ^{19}F shielding of a series of other molecules can be systematically determined. What is required are simultaneous accurate chemical shift measurements between the primary reference molecule and all the other molecules in the isolated molecule limit. Frequently, the primary reference molecule is not a convenient internal reference and a secondary reference molecule is used instead. In this case, the SiF_4 molecule is ideal, it is relatively inert, and has a long ^{19}F relaxation time in the gas phase so that the signal is sharp. To extend the ^{19}F absolute shielding scale, observed resonance frequencies in gas samples were reduced to the zero-density limit at 300 K using previously measured density and temperature-dependent chemical shifts for each gas. The results corresponding to a rovibrationally-averaged isolated molecule at 300 K are expressed relative to SiF_4 as a standard. The values of $[\sigma_0(300\text{ K}) - \sigma_0^{\text{SiF}_4}(300\text{ K})]/[1 - \sigma_0^{\text{SiF}_4}(300\text{ K})]$ were obtained by dividing the frequency differences by the resonance frequency of SiF_4 . The shielding differences $[\sigma_0^{\text{A}}(300\text{ K}) - \sigma_0^{\text{SiF}_4}(300\text{ K})]$ were obtained for a large number of molecules^{8,9} and were found to be identical to Hindermann and Cornwell's values for all of their molecules (six) which were included in the new set. Based on $\sigma_0(\text{HF}, 300\text{ K}) = 410.0\text{ ppm}$, absolute $\sigma_0(\text{SiF}_4, 300\text{ K}) = 363.2\text{ ppm}$. The absolute σ_0 for a large number of F-containing molecules have been determined from the ^{19}F chemical shift limit at 300 K, $[\sigma_0(\text{A}, 300\text{ K}) - \sigma_0(\text{SiF}_4, 300\text{ K})]$.^{8,9} Neat liquid CFCl_3 and C_6F_6 provide the connection for converting chemical shifts measured in other laboratories using these references into absolute shielding values; $\sigma(^{19}\text{F}$ neat liq. CFCl_3 , spherical, 300 K) = 188.7 ppm; $\sigma(^{19}\text{F}$ neat liq. C_6F_6 , spherical, 300 K) = 355.5 ppm.

How large can the errors be if the corrections shown in Figure 1 are not carried out, i.e. if $\langle C_{\text{gg}} \rangle_{v=0}/\langle B_{\text{gg}} \rangle_{v=0}$ are used to calculate $\langle \sigma_{\text{gg}}^{\text{p}} \rangle_{v=0}$ directly? The difference between the vibrational average of the ratios $\langle C_{\text{gg}}/B_{\text{gg}} \rangle_{v=0}$ and the ratio of the vibrational averages $\langle C_{\text{gg}} \rangle_{v=0}/\langle B_{\text{gg}} \rangle_{v=0}$ can be as much as 10% in molecules containing hydrogen. Incomplete knowledge of the first and second derivatives of C with nuclear configuration presently makes it impossible to correct for this error, as Hindermann and Cornwell had done for HF. The thermal average of σ^{p} can be approximated by using the spin-rotation tensor for the ground vibrational state. However, when a low-frequency vibration exists and the spin-rotation constants

Figure 1 Building up an absolute shielding scale from the absolute shielding of one primary reference whose spin-rotation constant is accurately known. The following notations are used: * denotes the primary reference molecule, A any other compound, subscript 0 the isolated molecule, and subscript e the equilibrium configuration

for the first excited vibrational state are substantially different from those of the ground vibrational state (such as in NNO), a proper thermal average has to be carried out. There are also rotational (centrifugal distortion) corrections which have to be made.

Given the possible sources of error which we have mentioned above, some discrepancies may be observed in comparing shielding values derived from spin-rotation constants with differences in thermal averages of shielding observed in nuclear magnetic resonance spectroscopy in the zero-pressure limit. However, the precision of most available spin-rotation constants is still such that the sources of errors discussed above are not limiting.

Ab initio calculations of the diamagnetic part of the shielding are generally reliable since these depend only on the ground-state wavefunctions. The changes resulting from configuration interaction are very minor, no more than a few tenths of a ppm in σ^d , over the Hartree–Fock value. Where ab initio calculations are not available, it is possible to estimate σ^d to within 1–2 ppm even without wavefunctions. Flygare has proposed an easy method for evaluating σ^d which has been shown to be sufficiently reliable for evaluating the average and the components of σ from the spin-rotation tensor.^{10,11} The success of this method is due to the fact that most of σ^d is given by the diamagnetic shielding of the free atom and the rest can then be approximately calculated by the method of atomic dipoles. It has been found that the method of Flygare and co-workers is accurate to within 1–2 ppm. Let us consider this method briefly.

By formally partitioning the sum of $1/r_j$ over all j electrons into two sums, one over electrons ‘on’ nucleus N and the other

over all electrons ‘on’ all the other nuclei, N' , Flygare has been able to write the average diamagnetic shielding in terms of a free atom term, a contribution of the electronic point charges centered at the other nuclei, and a third term which arises if the point charges are not centered on the N' nucleus but are displaced by a distance $\langle \rho \rangle_{N'}$:

$$\sigma_{av}^d = \sigma^d(\text{free atom}) + (\mu_0/4\pi)(e^2/3m) \sum_{N'} Z_{N'}/R_{N'} - (\mu_0/4\pi)(e^2/3m) \sum_{N'} R_{N'} \cdot \langle \rho \rangle_{N'}/R_{N'}^3 \quad (4)$$

The second term in the above equation is identical in form and opposite in sign to the nuclear terms in equation (1) and the last term is a small correction. Thus, the absolute shielding σ can be written in the Flygare method, as

$$\sigma_{av} = \sigma^d(\text{free atom}) - (\mu_0/4\pi)(e^2/3m) \times \sum_{N'} R_{N'} \cdot \langle \rho \rangle_{N'}/R_{N'}^3 + \frac{m_p}{2m_e g_N} \cdot \frac{1}{3} \sum \frac{C_{gg}}{B_{gg}^{(e)}} \quad (5)$$

This applies to the equilibrium configuration, with extension to thermal averages requiring some corrections which may be a few ppm.

Using the Flygare approximation for the diamagnetic shielding then leads to

$$\sigma_{av} \simeq \frac{m_p}{2m_e g_N} \cdot \frac{1}{3} \sum \frac{C_{gg}}{B_{gg}^{(e)}} + \sigma^d(\text{free atom}) \quad (6)$$

The diamagnetic shieldings of the free atoms are well known from the tabulations of Malli and Froese.³ For a spherical top molecule,

$$\left. \begin{aligned} \sigma_{av} &\simeq \frac{m_p}{2m_e g_N} \cdot \frac{C_{av}}{B} + \sigma^d(\text{free atom}) \\ \sigma_{||} - \sigma_{\perp} &\simeq \frac{m_p}{2m_e g_N} \cdot \frac{C_{||} - C_{\perp}}{B} \end{aligned} \right\} \quad (7)$$

and for a linear molecule

$$\left. \begin{aligned} \sigma_{\perp} &\simeq \frac{m_p}{2m_e g_N} \cdot \frac{C_{\perp}}{B} + \sigma^d(\text{free atom}) \\ \sigma_{||} &= \sigma_{||}^d \end{aligned} \right\} \quad (8)$$

since $\sigma_{||}^p$ is identically zero for a linear molecule.

The spin-rotation tensor has been used to determine the ^{15}N absolute shielding in NH_3 , ^{19}F in HF , ^{13}C and ^{17}O in CO , and ^{31}P in PH_3 , and these absolute shieldings have been used to establish all other absolute shieldings in various molecules containing these nuclei. Gas-phase studies provide the relative differences at the zero-density limit and these can be converted to $\sigma_0(300\text{ K})$ values absolutely. If the commonly used liquid reference is also measured relative to this one molecule, then all past and future measurements of chemical shifts relative to this liquid reference can be converted to absolute shieldings. As we have seen above, rovibrational corrections should be calculated and added to theoretical σ_e

before comparing with the experimental values $\sigma_0(300\text{ K})$. For some molecules this latter value is not very different from the zero-point vibrational average shielding $\sigma_0(0\text{ K})$. Similarly, the observed spin-rotation constants should be corrected for rovibrational effects before using the identity to obtain σ_e . Nevertheless, the agreement between absolute shielding values derived from spin-rotation constants and those from gas-phase measurements in the zero-pressure limit is remarkably good as shown in Figure 2, which indicates the reliability of the spin-rotation constants.

Figure 2 Experimental absolute shielding values of ^{19}F from gas-phase measurements in the zero-density limit. The gas-phase measurements are converted to absolute shielding by using HF as the primary reference molecule. These are compared with the individual absolute shielding values derived from independent measurements of the ^{19}F spin-rotation constants in various molecules

The ^{15}N absolute shielding scale is based on the spin-rotation tensor in the primary reference molecule, NH_3 . The spin-rotation-derived shielding for NH_3 is 264.54 ppm.¹² Nitrogen-15 chemical shifts in the gas phase taken to the zero-pressure limit lead to absolute $\sigma_0(^{15}\text{N})$ shieldings in the N_2 , NNO , and HCN molecules,¹³ see Table 1. At the same time, the absolute shielding of the liquid references were obtained: $\sigma(^{15}\text{N}, \text{NH}_3, \text{liq.}, 300\text{ K}) = 380.4\text{ ppm}$; $\sigma(^{15}\text{N}, \text{CH}_3\text{NO}_2, \text{liq.}, 300\text{ K}) = -135.8\text{ ppm}$.

The ^{17}O absolute shielding scale is based on the spin-rotation tensor in C^{17}O , $C_\perp = 30.4 \pm 1.2\text{ kHz}$ which leads to $\sigma(^{17}\text{O}, \text{CO}) = -42.3 \pm 17.2\text{ ppm}$.¹⁴ The gas-phase measurements of ^{17}O chemical shifts in H_2O , CO_2 , NNO , OCS , OF_2 , and CO lead to the absolute $\sigma_0(^{17}\text{O})$ shielding values¹⁴ shown in Table 2.

The ^{13}C shielding scale is based on the primary reference ^{13}C in the $^{13}\text{C}^{16}\text{O}$ molecule in which $C_\perp = 32.70 \pm 0.12\text{ kHz}$ in the $v = 0, J = 1$ state¹⁵ is in good agreement with the previous value of $32.59 \pm 0.15\text{ kHz}$. Rovibrational corrections on the spin-rotation constant to obtain $\sigma_e(^{13}\text{C in } ^{13}\text{C}^{16}\text{O}) =$

Table 2 Absolute σ_0 ^{17}O Shieldings

Molecule	$\sigma_0(^{17}\text{O in the molecule, 300 K})$ (ppm)
H_2O	344.0
CO_2	243.4
NNO	200.5
OCS	107.9
OF_2	-473.1
CO	(-42.3 ± 17.2)

3.0 ± 0.9 and then rovibrational corrections on the latter lead to $\sigma_0(^{13}\text{C in } ^{13}\text{C}^{16}\text{O}, 300\text{ K}) = 1.0 \pm 1.2\text{ ppm}$.¹⁶ With measurements of ^{13}C chemical shifts in the low-density gas phase under conditions such that intermolecular effects and bulk susceptibility effects are less than 0.05 ppm, the $[\sigma_0 - \sigma_0(\text{CO})]$ have been obtained for a large number of molecules ranging from CH_4 where $\sigma_0(^{13}\text{C}, \text{CH}_4, 300\text{ K}) = 195.1\text{ ppm}$ to $\text{CH}_2=\text{C}=\text{CH}_2$ where $\sigma_0(^{13}\text{CH}_2, 300\text{ K}) = 115.2\text{ ppm}$, $\sigma_0(^{13}\text{C}=\text{C}, 300\text{ K}) = -29.3\text{ ppm}$. The independent spin-rotation-derived absolute shieldings in $^{13}\text{CH}_4$, D^{13}CN , and O^{13}CS are completely consistent with the values of σ_0 obtained for these molecules based on $\sigma_0(^{13}\text{CO}) = 1.0 \pm 1.2\text{ ppm}$.

The $\sigma_0(^{13}\text{C in the molecule, 300 K})$ values for a large number of molecules have been published by Jameson¹⁶ and Jameson (Table 16).¹⁷ A missing value from the latter is isopentane $\cdots (\text{CH})\text{CH}_3$, for which $\sigma_0(^{13}\text{C in the molecule, 300 K}) = 165.0\text{ ppm}$. These measurements also provide $\sigma(^{13}\text{C}, \text{TMS liquid, spherical, 300 K}) = 184.1\text{ ppm}$ and $\sigma(^{13}\text{C}, \text{C}_6\text{H}_6 \text{ liquid, spherical, 300 K}) = 55.7\text{ ppm}$, which are convenient references for converting chemical shift measurements to absolute shieldings.

The ^{31}P absolute shielding scale is based on the primary reference molecule PH_3 , in which the spin rotation tensor $C_\perp = -114.90 \pm 0.13\text{ kHz}$ and $C_\parallel = -116.38 \pm 0.32\text{ kHz}$ (where the quoted errors are for 99% confidence limits),¹⁸ leading to $\sigma_0(^{31}\text{P}, \text{PH}_3, 300\text{ K}) = 594.45 \pm 0.63\text{ ppm}$. If the spin-rotation tensor is rovibrationally corrected, one gets¹⁹ $\sigma_e(^{31}\text{P in the PH}_3 \text{ molecule}) = 599.93\text{ ppm}$ and $(\sigma_\parallel - \sigma_\perp)_e = -64.5\text{ ppm}$.

The PF_3 molecule serves as a suitable secondary reference since its chemical shift has a smaller dependence on density. Extrapolation of gas-phase mixtures in argon to the zero-density limit provides the absolute shieldings²⁰ listed in Table 3. At the same time the absolute shielding of ^{31}P in convenient reference liquids has been obtained: $\sigma(^{31}\text{P}, 85\% \text{ H}_3\text{PO}_4 \text{ aq., spherical, 300 K}) = 328.35\text{ ppm}$ and $\sigma(^{31}\text{P}, \text{P(OMe)}_3 \text{ liquid, spherical, 300 K}) = 187.54\text{ ppm}$. A ^{33}S absolute shielding scale has been derived from the spin-rotation constant $C_\perp = 870 \pm 50\text{ Hz}$ in the OCS molecule, which leads to $\sigma_0(^{33}\text{S}, \text{OCS molecule}) = 843 \pm 12\text{ ppm}$.²¹ The ^{33}S chemical shift measurements in the gas phase lead (without full corrections for intermolecular effects) to the values shown in Table 4. A convenient liquid reference is CS_2 for which $\sigma(^{33}\text{S}, \text{CS}_2, \text{liquid, spherical, 300 K}) = 581\text{ ppm}$.

Although the proton absolute shielding for water was the first to be established, proton shifts have not been systematically measured in the gas-phase zero-pressure limit and connected to either liquid water or liquid TMS. This situation should be remedied soon as improving proton shielding calculations need some good experimental tests. There are, however, absolute shieldings that can be individually derived

Table 3 Absolute σ_0 ^{31}P Shieldings

Molecule	$\sigma_0(^{31}\text{P}$ in the molecule, 300 K) (ppm)
PMe_3	391.71
OPF_3	363.43
PF_3	222.69
PCl_2Me	138.65
PCl_3	111.29
P_4	-551.5
PH_3	(594.45 ± 0.63)

Table 4 Absolute σ_0 ^{33}S Shielding Values

Molecule	$\sigma_0(^{33}\text{S}$ in the molecule, 300 K) (ppm)

from measured spin-rotation constants by the methods already described, and these are shown in Table 5.

Table 5 Absolute σ_0 Proton Shieldings

Molecule	$\sigma_0(^1\text{H}$ in the molecule, 300 K) (ppm)	Other values (ppm)
CH_3F	28.27 ± 0.5	
PH_3	27.89 ± 0.15	
NH_3	32.10 ± 0.02	
H_2	26.363 ± 0.004	
CH_4	30.80 ± 0.23	30.611 ± 0.024
HCl	31.16 ± 0.09	
HF	28.64 ± 0.01	28.51 ± 0.20
H_2S	31.26 ± 0.40	
SiH_4	27.52 ± 0.44	27.63 ± 0.03

The errors quoted include only those arising from the uncertainty in the spin-rotation tensor itself. Other values reported in the last column are based on a variety of chemical shift measurements which are indirectly connected to liquid water whose absolute shielding is $\sigma(^1\text{H}, \text{H}_2\text{O}, \text{liq.}, \text{spherical}, 34.7^\circ\text{C}) = 25.790 \pm 0.014$ ppm.

4 THE CONNECTION BETWEEN ABSOLUTE SHIELDING SCALES OF TWO NUCLEI

Spin-rotation constants of any two nuclei in the same molecule can be related to one another provided that both nuclei relax entirely by the spin-rotation mechanism. In the gas phase, in the exchange-narrowing limit, there is a single characteristic correlation time τ which is identical for both nuclei.

The nuclear spin relaxation time characteristic of this mechanism is given by

$$(1/T_1)_{\text{SR}} = \frac{2}{3}(J(J+1))4\pi^2 C_{\text{eff}}^2 \tau \quad (9)$$

with C in units of rad s^{-1} , so that for two nuclei k and k' in the same molecule, in the same gas sample,

$$T_1(k)/T_1(k') = C_{\text{eff}}^2(k')/C_{\text{eff}}^2(k) \quad (10)$$

For linear molecules $C_{\text{eff}}^2 = C_{\perp}^2$. For spherical tops

$$C_{\text{eff}}^2 = C_{\text{av}}^2 + \frac{4}{45}(\Delta C)^2$$

$$= \left[\frac{1}{3}(2C_{\perp} + C_{\parallel}) \right]^2 + \frac{4}{45}(C_{\parallel} - C_{\perp})^2 \quad (11)$$

A nucleus in the center of a spherical top is a favorable choice since all $C_{\text{gg}}^{(k)}$ are equal by symmetry and only C_{av}^2 enters into the relaxation expression. If both nuclei k and k' relax entirely by spin rotation, and if C_{eff}^2 is known for one nucleus, e.g. ^{19}F in SeF_6 or TeF_6 , then C_{av} for the central nucleus (and thus the shielding) can be obtained from the measured ratio of relaxation times in the gas phase. This is supported by empirical observations for CH_4 in various buffer gases, in which the ratio of measured ^{13}C and ^1H relaxation times in the gas phase was found to be independent of buffer gas, temperature, or density, and was within experimental error of the inverse ratio of the C_{eff}^2 values from molecular beam data. These molecular beam data, in turn, were consistent with the ^{13}C shielding scale (based on $C_{\perp}$ in CO) and the ^1H shielding scale (based on γ of the H atom).

It is also possible to determine C_{eff}^2 from the density dependence of T_1 in the region of the minimum. However, for most systems, the minimum T_1 occurs at such low densities that appropriate measurements are feasible only for ^1H and ^{19}F nuclei which have the highest NMR sensitivity, and which also have well-established shielding scales based on spin-rotation constants from molecular beam and high-resolution microwave measurements.

This method was used to establish the ^{77}Se and ^{125}Te shielding scales by concurrent measurement of the ^{19}F and ^{77}Se (or ^{125}Te) spin-relaxation times in SeF_6 (or TeF_6) molecules in the dilute gas phase,²² and also the ^{29}Si shielding scale based on both SiH_4 and SiF_4 molecules.²³ The sample was gaseous (e.g. SeF_6 or TeF_6 , or an equimolar mixture of SiH_4 and SiF_4) contained in a sealed glass tube at a well-regulated temperature. Inversion-recovery experiments were set up in both the observe channel and the decoupling channel, the decoupling channel having been modified so that it could be tuned to ^{19}F as well as ^1H .

In one cycle, one-eighth of the total number of transients were taken and stored for each delay time for one nucleus and then the other. The next cycle went through the delay list for one nucleus and the other, acquiring the next eighth and so on. Thus the T_1 experiments were undertaken in the same molecule in the same sample essentially simultaneously. Only the magnitude of C could be obtained from the experiments. The signs were assigned on the basis of the σ values obtained. Defined with the gauge origin at the nucleus in question, σ^{P} is usually negative for most heavy nuclei. For SeF_6 the two possible values of σ^{P} which can be calculated from C are 1559.7 or -2160.7 ppm, from which we choose the latter, i.e. $C(^{77}\text{Se})$ is negative. For TeF_6 the two possible values of σ^{P} are 2570 or -3070 ppm and we choose the latter, which with a negative $g(^{125}\text{Te})$ implies that $C(^{125}\text{Te})$ is positive.

Although the relationship between σ^p and C is exact only for the rigid isolated molecule at its equilibrium configuration, we have used rovibrationally averaged values at room temperature for all quantities. The errors in σ associated with this are smaller than the rovibrational corrections to shielding (-8 and -9 ppm, respectively, for ^{77}Se and ^{125}Te in SeF_6 and TeF_6) since the vibrational corrections to C and σ^p tend to increase slightly the magnitudes of both. Hence, σ_0 (^{77}Se in SeF_6 molecule, 300 K) = 1437.8 ± 64 ppm, σ_0 (^{77}Se in H_2Se molecule, 300 K) = 2401 ± 64 ppm, and σ_0 (^{125}Te in TeF_6 molecule, 300 K) = 3790 ± 130 ppm.

These values are based on 3298 ppm and 6580 ppm for σ^d of the free Se and Te atoms, respectively, including relativistic corrections. Using the absolute shielding values for ^{77}Se in $\text{SeF}_6(\text{g})$ and for ^{125}Te in $\text{TeF}_6(\text{g})$, and the known gas-to-liquid shifts for SeF_6 and TeF_6 , the absolute shielding for the reference liquids $\sigma(^{77}\text{Se}, \text{Me}_2\text{Se}, \text{liq.}) = 2069$ ppm and $\sigma(^{125}\text{Te}, \text{Me}_2\text{Te}, \text{liq.}) = 4333$ ppm are obtained. Concurrent measurement of ^{29}Si and ^1H spin-relaxation times in a sample of SiF_4 gas provides the ratio $C_{\text{av}}^2(^{29}\text{Si})/C_{\text{eff}}^2(^1\text{H})$, and concurrent measurement of ^{29}Si and ^{19}F spin-relaxation times in SiF_4 gas provides the ratio $C_{\text{av}}^2(^{29}\text{Si})/C_{\text{eff}}^2(^{19}\text{F})$. The spin-rotation tensors are independently known for ^1H and ^{19}F in these molecules. Using $g_{\text{Si}} = -1.1106$ and the theoretical value for the diamagnetic shielding σ^d free Si atom = 874.1 ppm, and choosing positive signs for $C(^{29}\text{Si})$ in both molecules, leads to $^{29}\sigma_0(^{29}\text{Si}$ in SiH_4 molecule, 300 K) = 475.3 ± 10 ppm and $\sigma_0(^{29}\text{Si}$ in SiF_4 molecule, 300 K) = 482.0 ± 10 ppm.

The T_1 experiments in SiH_4 and SiF_4 provide two completely independent determinations of very nearly the same point (separated by only 6.7 ppm) on the ^{29}Si shielding scale. The coincidence of these two truly independent results is remarkable. Since a large part of $C_{\text{eff}}^2(^1\text{H}$ or $^{19}\text{F})$ is the isotropic average $C_{\text{av}}^2(^1\text{H}$ or $^{19}\text{F})$ which is directly related to $\sigma_{\text{av}}(^1\text{H}$ or $^{19}\text{F})$, the values are constrained to be consistent with the absolute shielding scales of both ^1H and ^{19}F and also the 6.7 ppm ^{29}Si shielding difference between SiH_4 and SiF_4 . All these conditions are well satisfied within realistic error estimates of ± 10 ppm. The ^{19}F shielding scale is well established, with several independent determinations based on the spin-rotation constants in a number of small molecules agreeing with the chemical shifts in the zero-pressure limit. The ^1H shielding scale is also well established on the basis of hydrogen atomic beam data. It is satisfying to find that the Si shielding scale is consistent with these. Finally, the measured ^{29}Si chemical shifts in SiH_4 and SiF_4 gas relative to neat liquid Me_4Si lead to $\sigma(^{29}\text{Si}, \text{Me}_4\text{Si}, \text{liquid, spherical}) = 368.5 \pm 10$ ppm.

In favorable systems, simultaneous measurements of T for two spin- $\frac{1}{2}$ nuclei in the same molecule in the gas phase provide a means of determining the absolute nuclear shielding scale of the second nucleus from that of the first. This method

can be applied when the spin-rotation tensor of the first nucleus is independently known or can be calculated from its known shielding tensor. The latter can be obtained by measurement of the chemical shift anisotropy and the isotropic absolute shielding based on some primary reference (such as ^1H in the H atom, ^{13}C in CO, ^{15}N in NH_3 , ^{17}O in CO, ^{19}F in HF, ^{31}P in PH_3 , or ^{33}S in OCS). In a linear molecule only the isotropic shielding is necessary since $\sigma_{\parallel}$ is entirely diamagnetic. For spherical tops the $(\Delta C)^2$ term is 4/45-times as small as the C_{av}^2 term, so that even when $(\Delta C)^2$ and $\Delta\sigma$ are unknown an estimate may be adequate. An appropriate molecule in which two nuclei relax nearly exclusively by spin-rotation in the gas phase effectively provides a bridge between the absolute shielding scales of these nuclei.

Finally, a method of obtaining the absolute shielding directly from the measured anisotropy $\Delta\sigma \equiv (\sigma_{\parallel} - \sigma_{\perp})$ in a linear molecule takes advantage of the symmetry requirement that the paramagnetic shielding contribution along the axis parallel to the molecular axis vanishes: $\sigma_{\parallel}^p = 0$. A theoretically calculated diamagnetic term $\sigma_{\parallel}^d$ provides the rest of the required information:

$$\sigma_{\perp} = \sigma_{\parallel}^d - \Delta\sigma, \quad \sigma_{\parallel} = \sigma_{\parallel}^d \quad (12)$$

so that the absolute average shielding is

$$\sigma = \sigma_{\parallel}^d - \left(\frac{2}{3}\right) \Delta\sigma \quad (13)$$

albeit containing some unwanted intermolecular effects in $\Delta\sigma$ which is usually obtained from a condensed-phase measurement. One can therefore establish a shielding scale for a nucleus by choosing an appropriate linear molecule. Some examples are shown in Table 6. The absolute shieldings obtained from the anisotropy differ slightly from those obtained in the gas in the zero-pressure limit, from which we see that intermolecular effects are 1 to -8 ppm in the solid. It should be noted that the above relationships hold only for a linear molecule, not for a quasilinear or pseudolinear molecule. Any off-axis atoms break the symmetry and lead to $\sigma_{\parallel}^p \neq 0$. For example, $\text{CH}_2=^{13}\text{C}=\text{CH}_2$ has $\sigma_{\parallel}^p = -250$ ppm for the central ^{13}C . Furthermore, $\sigma_{\parallel}^p = 0$ holds for a linear molecule only at the level of the nonrelativistic theory of shielding.

5 MAGNITUDES OF THE CORRECTIONS LINKING THE SHIELDING IN THE CONDENSED PHASE TO THE ISOLATED MOLECULE AT ITS EQUILIBRIUM GEOMETRY

The exquisite sensitivity of the shielding to the electronic environment is what makes the NMR chemical shift a very

powerful tool in studying structure, intermolecular effects, and dynamic averaging. For the purpose of comparing with theoretical *ab initio* calculations of the shielding, however, this exquisite sensitivity to the environment appears at first to be a distinct disadvantage. Nevertheless, if one knows the precise relationship between the quantities being calculated (the shielding at some specific set of nuclear coordinates) and the quantities being measured, then the appropriate comparisons against theory can still be made. In fact, a more complete comparison becomes possible when the true connection between the experimental milieu and the theoretical constructs is understood. Since it is never possible to observe a molecule as a fixed arrangement of nuclei (even in the molecular beam where no neighbor effects need to be considered, there is always at least the zero-point vibrational motion), let us consider the nature of the connection between what is measured and what can be calculated. In this respect, the NMR chemical shift is in by far a more advanced stage compared with other molecular electronic properties such as electric dipole polarizability, electric field gradient tensors, etc. It is partly a theoretical advantage, but more important an experimental advantage, that NMR spectroscopy provides. The very high resolution that is possible under the conditions of isotropic averaging in gases and solutions makes it possible to measure chemical shifts of the order of parts per billion. The more advanced temperature control of experiments in NMR spectroscopy, compared with other forms of spectroscopies, combined with the high resolution, has made it possible to measure the temperature dependence of the shielding in a nearly isolated molecule over a 200 K range almost routinely. The small chemical shifts that are the differences in shielding between two molecules differing only in the isotopic masses of some of the nuclei can be measured to a few ppb as well.

Both of these phenomena are related to the dynamic averaging of the vibrating molecule through its various nuclear configurations, each configuration having its appropriate shielding value for a particular nucleus. There are also intermolecular effects, again associated with shielding values that change with nuclear configurations, this time the configurations of supermolecules including not only the molecule bearing the NMR nucleus but all the neighboring interacting molecules. Solvent shifts are a manifestation of this, as are adsorption shifts, as well as a portion of the discrimination between different locations of the same amino acid residues in a protein. The dynamic averaging is discussed further in *Isotope Effects on Chemical Shifts and Coupling Constants* and some aspects of the intermolecular shifts are discussed further in the article on *Gas Phase Studies of Intermolecular Interactions and Relaxation*. In this article, we merely take note of the mechanisms that give rise to the phase-dependent and temperature-dependent differences and how large the corrections are.

Let us first consider an isolated or nearly isolated molecule, i.e. one in which the frequency of collisions with other molecules is still enough to allow the molecule to sample its many rotational and vibrational states while being observed in the NMR spectrometer but not frequent enough to lead to a measureable intermolecular contribution. As the molecule undergoes vibrations, the distances between nuclei change in a periodic fashion, bonds being alternately compressed and expanded, bond angles being alternately enlarged and made smaller, with torsions or frustrated internal rotations possibly occurring as well. For each frozen configuration the

shielding of an NMR nucleus in the molecule is different. In the context of the Born–Oppenheimer approximation, the nuclei are moving slowly enough relative to the electronic motion that it is possible to talk about a shielding surface, a highly multidimensional mathematical surface akin to the intramolecular potential energy surface, which describes the shielding at each configuration of the collection of nuclei that make up the framework of the molecule. Of course, the parts of this shielding surface that are sampled during the vibrations are those regions that correspond to the deep pockets in the intramolecular potential energy surface (PES), located at what we call the ‘equilibrium’ molecular geometry. Thus, it would seem that for the most part, the only interesting regions that we should concern ourselves with are those in the immediate vicinity of the single deep pocket in the PES. This may indeed be the case for the dynamic averaging in small molecules such as diatomics and methane. However, as soon as torsion angles come into the picture, the nature of the averaging changes. Wider excursions are possible, perhaps passing through *cis*-eclipsed, *gauche*, *gauche'*, *trans*-staggered, etc. Even in a simple molecule like NH₃, the umbrella inversion has to be considered in its entirety—no minor small amplitude excursions here! Thus, it becomes necessary to think in terms of not a single shielding tensor associated with a particular nucleus in a molecule, but a continuum, of such tensors changing smoothly with nuclear displacements away from the lowest energy point in the deep pocket. Some shielding surfaces are shown in the article on *Isotope Effects on Chemical Shifts and Coupling Constants*, and the consequences of the dynamic averaging are discussed there as well.

How large are the shielding changes in going from the equilibrium geometry to the dynamically-averaged shielding? This depends on the molecule. For the ¹⁹F shielding in the F₂ molecule, the difference is of the order of 40 ppm; for the ¹⁵N in the N₂ molecule it is smaller, about 3 ppm, and for ¹H in the HF molecule it is around 0.3 ppm. Most of the dynamic averaging effects lead to a decreased shielding, but instances of increased shielding can also be found. At the time when the theoretical calculations were only good to within 50 ppm for ¹³C in various molecules, for example, the direct comparison of the shielding calculated in a molecule rigidly fixed at its equilibrium geometry with the chemical shift measurements in solution could be excused. With the present theoretical capability discussed in the articles by Hansen and Kutzelnigg in this Encyclopedia, the real test of the quality of a calculation is really in the shape of the surface in the immediate vicinity of the equilibrium geometry, not just the value at a single one point on the surface. The rationale for determining absolute shielding scales is to be able to compare shieldings rather than differences of shieldings between two different molecules, thereby disallowing any fortuitous agreements in chemical shifts while the shieldings themselves could be far off. We go further at this point and make note not only of the absolute shielding of a nucleus in the particular molecule, but the dynamic average over a portion of the shielding surface for this nucleus; the shape of the surface itself is being tested. Typical magnitudes of the vibrational corrections that arise from this dynamic averaging are shown in Table 7.

Most of the time, we observe molecules in some medium rather than in the zero-pressure limit in the gas phase. Most of the full shielding tensor information is obtained in the solid

Table 7 Vibrational Corrections from Dynamic Averaging

^{77}Se in H_2Se	-58.9

state or in liquid crystal solutions. It is therefore important to understand the ways in which that which we are measuring is affected by the surrounding molecules. We know that medium effects can be large because the gas-to-liquid shifts have been measured in pure substances. The magnitudes of some of these are shown in Table 8, where the chemical shift between the liquid and the vapor in equilibrium with it have been measured at the same temperature. We also know that intermolecular effects in physisorption can be large. Now, this is strictly an intermolecular effect, not involving a change in chemical structure. For ^{129}Xe nuclei of xenon atoms physisorbed in zeolites, the adsorption shifts are of the order of several hundred ppm! In other words, a xenon atom adsorbed in a zeolite cavity or channel has a shielding that differs from that in the gas phase by several hundred ppm. (See *Adsorbed Species: Spectroscopy and Dynamics*.) This is strictly an intermolecular effect, not much different from the solvent effect in solution, with the only difference being that the solvent is stationary while the solute is relatively free to move. This too is a result of dynamic averaging, just as in solutions. This is clearly a many-body type of situation and the interpretation involves making some approximations.

^{129}Xe in	Xe	244	-200

A simpler situation is found in the gas phase. Intermolecular effects can be treated in the gas phase by the method of Buckingham and Pople by considering a virial expansion of the molecular electronic property, in this case the NMR shielding, in powers of density, i.e. $\sigma(T, \rho) = \sigma_0(T) + \sigma_1(T)\rho + \sigma_2(T)\rho^2 + \sigma_3(T)\rho^3 + \dots$, where $\sigma_0(T)$ is the temperature-dependent shielding in the nearly isolated molecule. By making measurements of the shielding in gas samples of various densities at various temperatures, it is possible to obtain directly the second virial coefficient of nuclear shielding, $\sigma_1(T)$. This is a dynamic average which has a precise interpretation, as shown below.

$$\sigma_1(T) = \int_0^\infty 4\pi R^2 dR [\sigma(R) - \sigma(\infty)] \exp^{-V(R)/kT} \quad (14)$$

In other words, the dynamic averaging occurs over an intermolecular shielding surface, $[\sigma(R) - \sigma(\infty)]$, with various weighting factors, as determined by the intermolecular potential energy, $V(R)$, surface. In a sense, this is entirely analogous to the averaging which occurs in vibration, except that the pockets are very deep in the intramolecular potential surface, whereas they are relatively shallow for intermolecular surfaces. Thus a very wide range of distances are included, and the temperature dependence is explicitly seen in the integration. The intermolecular shielding surface looks rather similar to the shielding surface of a nucleus in a diatomic molecule, except that all parts of the intermolecular surface are important other than at very very close range where the repulsive interactions dominate so strongly that such configurations are not effectively sampled.

This shielding surface is also amenable to theoretical calculations. In effect, the system under consideration is a supermolecule made up of the interacting molecules at all possible orientations and separations. A direct comparison of an intermolecular surface to an intramolecular one is not possible. However, the known differences in shielding sensitivities of nuclei across the Periodic Table allow us to scale the chemical shifts of one type of nucleus relative to another. For example, proton shifts are about 20 ppm to the fluorine shifts of about six hundred ppm. If we do this, then we can put an intramolecular shielding surface on the same plot as an intermolecular shielding surface, keeping their magnitudes in the same proportion as the well-known relative magnitudes of the ranges of their chemical shifts. One such example is shown in Figure 3, where the intramolecular shielding surface for the ^{23}Na nucleus in the NaH molecule is superimposed on the intermolecular shielding surface for the isoelectronic system, the ^{21}Ne nucleus in a Ne atom interacting with a He atom. On an absolute scale the shielding surface for ^{21}Ne in Ne-He has a much steeper change than the ^{23}Na shielding surface, but only because the nuclei on the right-hand side of the Periodic Table have much larger expectation values for the $1/r^3$ value of the electrons. When this is taken into account, it is seen that intramolecular shielding surfaces involve a much greater response of the nucleus to the changing electronic environment (bond extension or compression) than the response of the nucleus to the approach of a neighboring solvent molecule described by the intermolecular shielding surface.

If the shielding of a nucleus in a molecule surrounded by six neighbors, say, can be considered as a sum of six pairwise contributions between itself and each neighbor molecule,

Figure 3 The intramolecular shielding surface for ^{23}Na in NaH and the intermolecular shielding surface for ^{21}Ne in NeHe

and if each pairwise intermolecular shielding function is known (similar to the ^{21}Ne shielding function for NeHe in Figure 3), then dynamic averaging amounts to sampling all such configurations of molecule and neighbors and calculating the intermolecular shielding for each configuration. This has been done for ^{129}Xe shielding in zeolite NaA. The same intermolecular shielding function that reproduces the $\sigma_1(T)$ for xenon in the gas phase reproduces the chemical shifts between the Xe, Xe_2 , Xe_3 , ..., Xe_8 clusters trapped inside the cages of zeolite NaA.^{24,25} In principle, chemical shifts in condensed phases can be obtained by a similar dynamic averaging.

1 INTRODUCTION

The determination of the structure of an unknown chemical compound is one of the prominent application areas of NMR. The overwhelming number of elucidations are performed by experienced spectroscopists without the help of automated or computer-assisted tools for such data analysis. The goal of computerization of NMR-based structure elucidation is to reduce the need for human intervention over computer assistance to automated systems to obtain an ease-of-use comparable with structure determination using X-ray crystallography. This article presents the basic computerization approaches for the individual structure elucidation phases.

The structure elucidation process can be subdivided into the data acquisition, the data interpretation, and the structure generation and evaluation. The data acquisition is well understood and reasonably well automated. The challenge for the analysis of one-dimensional (1D) NMR spectra arises from the inherent ambiguity between spectral features and the molecular structures. Three basic computerized 1D analysis techniques are discussed: the database search, the knowledge-based approach, and the pattern-recognition approach. The advantage of multidimensional NMR techniques is a significant reduction in the ambiguity of the spectral–structural relationship. However, the size of the resulting datasets and the frequently minimal signal-to-noise (S/N) ratio of the data pose problems for both manual and automated analyses alike. The automated analysis of multidimensional data is described using two-dimensional (2D) INADEQUATE spectra which allow the direct detection of the molecular carbon skeleton.

The results of the spectral data interpretation are identified molecular fragments and/or constraints on the possible structure of an unknown compound. Computers are ideally suited to piece together the structural information from various sources and to generate exhaustively all possible candidate structures of the unknown which are compatible with the available constraints. The list of all candidate structures provides a powerful means of identifying the scope of the remaining structural ambiguities. Due to the lack of available software, the structure evaluation and the identification of additional experiments to discriminate among remaining candidates

still requires an experienced spectroscopist. A proper structure elucidation would iterate through the data acquisition, interpretation, structure generation, and evaluation until all but one candidate structure have been ruled out.

2 COMPUTERIZED ANALYSIS OF ONE-DIMENSIONAL SPECTRA

^{13}C spectra offer the most prominent applications for 1D NMR structure elucidations and are used here to introduce the database search, the knowledge-based and the pattern-matching approaches for 1D computerized spectral analysis.

The simplest application of ^{13}C spectra is as a molecular fingerprinting tool. For example, many molecules encountered in natural products are known compounds, and a computerized search in a spectral database may be used to locate the matching reference spectrum and to identify the given compound. Unfortunately, maintaining quality spectral databases is extremely expensive and only a limited number of known compounds can be found in publicly available spectral databases.¹ Nevertheless, even if the spectrum of the unknown is not among available reference data, closely matching spectra might provide clues about the structure of an unknown compound. Besides complete spectrum matching, it is possible to match selected features. A prominent example is the identification of monomer units in a polymer sample by matching the polymer's spectrum against a database of monomer spectra. Despite the obvious limitations, spectral database searches remain the method of choice for most compound identifications.

Closely related to the human analysis of 1D spectra are the knowledge-based approaches ('artificial intelligence methods') for computerized spectral analysis. A correlation table of molecular substructures and related chemical shift ranges (possibly including resonance multiplicities) can be assembled to describe the substructure–subspectral relationship. Normally some 200 substructures will be used, each describing molecular fragments such as $>\text{CH}-\text{O}-$ with one central ^{13}C resonance and the immediate neighboring atoms. Enlarging the size of the substructures would allow one to specify better the environment of a nucleus of interest and, thereby, to narrow the corresponding resonance range. Enlarging the size of substructures to two resonance fragments, unfortunately, would require tens of thousands of table entries.

By analogy with human use of such correlation tables, a rule-interpreter program can use these table entries ('rules') in a hypothesis-driven or data-driven manner to find all possible constituent substructures consistent—when considered individually—with the experimental spectrum. In its simplest form a data-driven rule interpreter would examine each observed spectral resonance signal and list all matching substructures found in the correlation table. Due to the ambiguities in the substructure–subspectral relationship, many more substructures will be identified in this first analysis step, which are consistent with a given 1D spectrum than are actually present in the unknown. A substructure not only specifies the central atom with a given resonance range but also imposes constraints on the possible environment of neighboring atoms. In the second analysis step elaborate consistency checks can identify mutually consistent sets of possible substructures.

Such knowledge-based interpretation schemes for 1D data are generally fast and provide a valuable insight into the possible structure of an unknown. However, it is unrealistic to expect such simple rule-based schemes to compete successfully with the careful spectral analysis carried out by an experienced spectroscopist. A spectroscopist often uses—consciously or subconsciously—background information, such as general chemical knowledge, the source and assumed class of the unknown, previous experience with similar structures, etc., in addition to the spectral data to add to the spectral analysis and to resolve ambiguities encountered during the data interpretation. This additional information is normally not stored in the rule base and hence is unavailable to the automated interpretation process.

The major limitation of database searches is the unavailability of critical reference spectra, and the major limitation of knowledge-based approaches is a lack of sufficient models to understand and describe the substructure–subspectral relationship. A set of methods, designed to overcome these limitations, involves the derivation of model-free classification rules from database reference spectra. These are known as ‘pattern-recognition approaches’ and differ radically from any human interpretation scheme in that they do not assign a physical meaning either to individual spectral resonances or to any relationship between individual measurements. An NMR spectrum is regarded as a vector representing a single point in an abstract n -dimensional pattern space. For example, a ^{13}C spectrum might be represented by a 200-dimensional vector with each dimension corresponding to a 1 ppm range in the spectrum. Each dimension corresponding to a spectral range with one or more signals is set to 1 and otherwise to 0. In this description each spectrum representing a single point in the assumed 200-dimensional vector space can be compared with a reference spectrum by some abstract distance measure or can be compared with predetermined threshold values.

With this formalism, empirical classifications can be determined from a database of reference spectra (the ‘training set’) which allow one to make a single binary decision, such as distinguishing between the presence and absence of a molecular feature from a given spectrum. Once determined, such classification criteria can be readily applied to spectra of unknown compounds. For example, the possible presence or absence of the $>\text{CH}-\text{O}$ -substructure would be decided using knowledge-based approaches by searching for a carbon resonance (a signal doublet if no proton decoupling is used) around 75 ppm in the ^{13}C spectrum. In contrast, a pattern-recognition procedure would subject the complete spectrum to some mathematical transform and the resulting number would be compared with a cut-off value determined from reference data to establish the presence or absence of the $>\text{CH}-\text{O}$ -substructure. The applications of pattern-recognition methods to NMR data generally have not proven to be of great utility for automated structure elucidation. The major problem is that a classification may indeed be right or wrong but pattern recognition has failed to provide a real justification or confidence estimate for the proposed classification.

Details of the above discussed approaches as well as a description of existing programs can be found in a book by Gray.² The goal of the computerized structure elucidation process is the exhaustive generation of possible molecular structures satisfying all constraints. For the structure generation phase only those substructures and structure

constraints determined beyond reasonable doubt should be used in the generation process. The highly ambiguous nature of 1D spectral interpretation results gives the ultimate justification for the use of less ambiguous multidimensional NMR data in the structure elucidation process.

3 AUTOMATED ANALYSIS OF TWO-DIMENSIONAL INADEQUATE SPECTRA

The most useful multidimensional NMR spectra for structure elucidation are the homonuclear and heteronuclear short-range and long-range correlation spectra.³ Multidimensional datasets are often acquired with a minimal S/N ratio and are often of the maximum size which the available computer storage allows one to acquire. The manual interpretation of such data is extremely tedious and is normally the time-determining step in the structure elucidation of an unknown compound. No computer assisted structure elucidation system can be considered complete without automation of this crucial step.

Computer assisted or automated techniques for interpreting 2D NMR spectra have consisted mainly of the application of direct techniques⁴ (e.g. cluster analysis and peak picking), linear prediction or maximum entropy methods,⁵ or least-squares parameter optimization⁶ in the case of severe overlap and/or strong coupling. If signals are strongly overlapping, a model can help to resolve ambiguities and also significantly improves the detection limit of the spectral analysis.

The greatest challenge in the structure elucidation of complex molecules is the determination of the molecular carbon skeleton. A method which allows the direct detection of carbon–carbon bonds is the two-dimensional version of the INADEQUATE experiment.⁷ A single spectrum frequently allows one to trace the complete carbon skeleton of a molecule. Unfortunately, difficulties with the insensitivity of the method at natural abundance of ^{13}C (1.1%), the resulting long acquisition times of these spectra, the size of the acquired two-dimensional data sets, and the time-consuming and error prone manual interpretation of often hundreds of megabytes of data have severely limited the routine use of this technique. Two-dimensional INADEQUATE spectra are used here to illustrate automated spectral analysis allowing one to improve the sensitivity, reliability, and speed of the spectral interpretation.

Figure 1 shows a graphical illustration of the 2D INADEQUATE spectrum for a $>\text{CH}-\text{CH}_2-\text{CH}_3$ molecular fragment with the corresponding proton decoupled ^{13}C spectrum. The first bond pattern is found around the chemical shifts ν_A and ν_B as two pairs of antiphase doublets at the double quantum frequency (DQF) $\nu_A + \nu_B$. The second bond pattern belongs to the methylene (ν_B) and methyl (ν_C) carbons, but no bond signal can be found between the methine (ν_A) and methyl carbons (ν_C) in agreement with the bonding in $>\text{CH}-\text{CH}_2-\text{CH}_3$.

The major challenge for every computerized analysis of multidimensional data is rapid and reliable data reduction. Through the automated analysis of the 1D spectrum all carbon resonance frequencies as well as linewidths and intensities can be easily determined. For the interpretation of 2D INADEQUATE data for each pair of resonances identified in the 1D spectrum, two small regions of the spectrum can be defined as shown by the small rectangles in Fig. 1. If a bond exists between the two carbon atoms under consideration,

Figure 1 Schematic representation of a 2D INADEQUATE spectrum of a $-\text{CH}-\text{CH}_2-\text{CH}_3$ fragment. (Reproduced by permission of the American Chemical Society from R. Dunkel, C. L. Mayne, R. Pugmire, and D. M. Grant, *Anal. Chem.*, 1992, **64**, 3134)

the characteristic pattern must exist within this 'bond area' which typically comprises less than one-thousandth of the whole spectrum. For n carbon atoms there are $n(n-1)/2$ possible bond regions to be examined. To maximize the sensitivity of this computerized spectral analysis a model equation is used describing the functional form of a possible bond signal.

Two bonded ^{13}C atoms form an AB (or AX) spin system producing four transitions in the shift direction of the 2D INADEQUATE spectrum. From the quantum mechanical description of an AB system all four resonance frequencies and the relative transition intensities can be calculated from the resonance frequencies, ν_A and ν_B , and the one-bond $^{13}\text{C}-^{13}\text{C}$ coupling constant J . The INADEQUATE pulse sequence uses a double quantum filter to suppress the unwanted and isolated ^{13}C resonances and this filter leaves the four transitions in antiphase. When the difference between the resonance frequencies ν_A and ν_B is large compared with the coupling constant J , the spin system simplifies from AB to AX. For the AX spin system all four transitions have the same absolute intensity, each antiphase doublet is centered at the chemical shift of the corresponding carbon atom, and the doublets are each split by the one-bond $^{13}\text{C}-^{13}\text{C}$ coupling constant, as shown in Figure 1.

The 2D INADEQUATE lineshape may be calculated as the product of the 1D shift and double quantum lineshapes. These lineshapes themselves are modeled as a convolution of a Lorentzian function caused by exponential spin relaxation and a sinc function caused by truncated data acquisition.

To obtain the best possible spectral resolution multidimensional spectra are normally acquired with phase sensitive detection and hence have to be phase corrected before undertaking any manual data analysis. By introducing phase parameters in the analysis model, phase sensitive experimental data can be analyzed without prior phase correction. For each 1D lineshape function a phase parameter is introduced in the model equation specifying the linear combination of absorption and dispersion modes needed to explain the observed spectral phase. Phase sensitive 2D spectra consist of hypercomplex data with four phase quadrants (real/real, real/imaginary, imaginary/real, imaginary/imaginary). Visual interpretation of 2D spectra is limited to the analysis of one quadrant. The only difference between the signals in the different phase quadrants

is a phase shift of 90° between the real and imaginary part in each spectral dimension. Hence, the model equation describes all four quadrants and, since the phase relationship between the phase quadrants is known, all quadrants can be analyzed simultaneously without introduction of additional model parameters. Even though the signals across all four quadrants are correlated, the noise between the quadrants should be uncorrelated, at least partially. Hence, the simultaneous computer analysis of all four quadrants achieves an effective S/N improvement over the analysis of only one quadrant.

The derived model equation describes the shape of all possible bond signals as a function of a few physically defined quantities. Most of the model parameters are known from acquisition parameters and values obtainable from the prior analysis of the 1D carbon spectrum. Using nonlinear regression analysis, the few not-exactly-known model parameters can be determined for each possible bond pattern by fitting the model equation to the corresponding small bond regions of experimental data.

The top spectrum in Figure 2 shows the imaginary/imaginary phase quadrant of the unphased bond signal of carbon atoms 2,3 in 1,1-dimethyltetralin (1,2,3,4-tetrahydro-1,1-dimethylnaphthalene) in a high S/N 2D INADEQUATE spectrum. Regressing the complete hypercomplex data (not just the phase quadrant shown) of this bond signal with the model equation yields the best-fit parameter values. The parameter values can then be used to simulate the signal in the imaginary/imaginary phase quadrant (as shown in the spectrum in the middle of the figure); the bottom spectrum shows the difference between the experimental and the simulated spectra. The residuals between both signal doublets are caused by incomplete suppression of isolated ^{13}C resonances by the INADEQUATE pulse sequence and are unrelated to the analyzed bond signal.

Regressing all potential bond areas in a 2D INADEQUATE spectrum using the described model equation reduces the 2D INADEQUATE information from potentially hundreds of megabytes of spectral data to $n(n-1)/2$ sets of determined best-fit model parameters. The remaining step is to identify those parameter sets describing genuine bond signals. An excellent scale invariant bond criterion is the determined overall intensity value of a spin system scaled by its error value. The related parameter precision defined as the inverse relative error of the measurement⁸ of the overall intensity value is used as the sole bond criterion for the following discussion.

To determine the detection probability for the bond pattern shown in Figure 2 at a root-mean-square (rms) S/N ratio of 2.5, 1000 bond regions with pure pseudorandom noise and 1000 bond regions with noise, and the hypercomplex simulated signal from Figure 2 at the appropriate S/N level are generated. The top spectrum in Figure 3 shows one of the generated bond signals in the imaginary/real phase quadrant which shows the highest S/N ratio of the four quadrants. The simulated spectra may be analyzed like experimental data to obtain the intensity parameter precision of each simulated bond region. The bottom spectrum in Figure 3 shows the best-fit determined bond signal for the bond region shown above. The distribution of determined intensity parameter precisions determined from this Monte Carlo simulation of bond signals is shown as the white distribution in Figure 4. The bimodal noise-only distribution is shown in black. One thousand simulations

Figure 2 Unphased 2D INADEQUATE bond signal of carbon atoms 2,3 in 1,1-dimethyltetralin in the imaginary/imaginary phase quadrant of: (top) the experimental spectrum; (middle) the simulated spectrum; (bottom) the residual spectrum. were used to approximate a 99.9% detection probability. Since the distributions do not overlap each other, bond signals can be distinguished from noise patterns with a probability greater than 99.9% at the r.m.s. S/N level of 2.5, which is inconceivable for the visual interpretation of the data. This illustrates the dramatic sensitivity increase obtainable through computerized spectral analysis. Using Monte-Carlo simulations the detection limit of the method at a requested certainty level can be determined for all conceivable model equations, parameter values of experimental patterns, spectral resolutions, and analysis strategies.

Slight extensions of the described computerized analysis have to be made to account for signal aliasing, to guarantee convergence to the correct bond signal in high resolution spectra, to detect rare but possible ambiguities in the 2D INADEQUATE signal assignments, and to list all possible interpretations of identified ambiguous signal assignments. The described automated analysis of 2D INADEQUATE spectra with these extensions is implemented in program XCCBond⁹ and has been applied mainly to the structure elucidation of natural products.¹⁰ On typical spectrometer workstations a 2D INADEQUATE spectrum can be analyzed in a few minutes for a 30-carbon-atom compound, using a few thousand spectral points resolution in each dimension.

4 STRUCTURE GENERATION

The interpretation results of the analysis of NMR spectra are identified substructures and/or structural constraints for the unknown. For example, in the case of the described automated 2D INADEQUATE spectral analysis the interpretation results are identified carbon-carbon connectivities. Due to heteroatoms in the molecular backbone or due to limitations of the 2D INADEQUATE experiment, only separated carbon

skeleton fragments might be detected rather than the complete molecular backbone. The remaining problem, therefore, is to find in an automated and uniform approach the molecular structures that are consistent with the identified fragments.

No intuitive procedure exists which would allow a spectroscopist to produce manually all possible molecular isomers consistent with given constraints. The success of the structure elucidation, however, depends on carefully ruling out all possible candidate structures of the unknown until only one possible structure remains. An overlooked or not properly ruled-out isomeric structure renders the final result of the structure elucidation meaningless. A computer is ideally suited for the exhaustive generation of possible isomeric structures subject to given bonding constraints, because it is a purely combinatorial problem. Lederberg¹¹ has proven that the topology of any chemical compound can be defined in terms of 'tree' and 'vertex' graphs. The resulting vertex graph programs were the first provably correct exhaustive structure generators. The remaining challenge is to obtain a reasonable efficiency of exhaustive structure generators for typical structure elucidation applications.

In principle, a simple recursive algorithm could be used to list all possible isomeric structures consistent with the molecular formula of the unknown (usually obtainable through mass spectrometry) by an exhaustive exploration of all possible bonds among the atoms. In a second step those isomers consistent with all constraints could be filtered out and duplicate isomers eliminated. Unfortunately, the combinatorial explosion of the number of possible isomers swamps such brute-force approaches. A practical strategy is to generate only those structures consistent with the known constraints and also to avoid duplicate structures rather than to generate isomers which have to be discarded later.

Section 3 describes the computerized analysis of 2D INADEQUATE spectra. The output of the analysis program XCCBond is a carbon-carbon connectivity table. Given the molecular formula of the unknown, this connectivity table can be expanded to contain the noncarbon atoms. A simple recursive algorithm can then be used to complete this partially completed connectivity table by determining all permutations of bonds between the free valences of the specified 'fragments'. This approach guarantees that all resulting isomers (represented by alternate connectivity tables) will satisfy all determined carbon-carbon connectivities and all additional constraints (e.g. the number of protons for each carbon atom) enforced during the completion of the connectivity table.

Each possibility of forming a bond during the completion of the connectivity table starts a new search tree which a simple recursive algorithm would explore exhaustively. However, before assuming the presence of a bond a simple analysis would often reveal that the resulting search tree cannot lead to useful isomers. For example, the analysis could show that the whole search tree can only lead to disconnected molecular substructures. A structure generator should detect and prune such fruitless search tree branches as soon as possible.

Another source of inefficiency in the structure generation is multiple generated copies of an isomer most commonly caused by molecular symmetry. The described algorithm would, for example, list a phenol molecule six times with the hydroxy group located at each of the six carbon atoms of the benzene ring. A possible solution to multiple isomer copies is

subsequently to transform all generated isomers to a canonical form and to remove duplicates. More efficient is to transform the connectivity table itself into a canonical form to be able to detect and exploit symmetries during intermediate generation steps.

The structure generators described in the literature differ greatly in their algorithms, capabilities to prune fruitless search trees, and approaches to avoid redundancy in the generated isomers. An example program for the described structure generator for the completion of a partially specified connectivity table, allowing one to specify simple additional constraints and pruning search trees leading to disconnected molecular fragments as well as a comparison of published structure generators, can be found in the book by Gray.¹²

1 INTRODUCTION

Much of the progress in NMR spectroscopy over the past 50 years has rested on significant advances in instrumentation and computer hardware and software technologies. There has been an extraordinary transition from the early NMR instruments to today's modern systems. In the mid-1990s, NMR spectrometers are based on multiple computers, mostly tightly coupled, and associated peripherals and smart devices. Software available for control of modern day NMR experiments, and for processing and analysis of the results of those experiments, has reached sophistication that could not be anticipated a decade ago. It is anticipated that, near the turn of the century, NMR instrumentation itself may become truly intelligent, assisting scientists in performing complicated analysis of molecular structures and other applications. Parallel to the developments in NMR spectroscopy have been extraordinary opportunities demonstrated in magnetic resonance imaging (MRI) methods, used in both clinical modalities and the material sciences.

This chapter describes the historical development of computing hardware and software technologies in NMR, with emphasis on current state-of-the-art data processing and data analysis for NMR spectroscopy, and its applications in chemistry, biology, and related sciences. Today, NMR data processing methods greatly extend the utilization of NMR data across a broad range of applications, from industrial process control, to organic and biological molecular structure determination, to understanding basic dynamic properties of molecules.

2 HISTORY OF COMPUTERS IN NMR

The earliest use of digital computers in NMR was for time-averaging of multiple scans, using hard-wired transient recorders in the mid-1960s (the Varian CAT) and then yielding to hybrid systems performing the first Fourier transforms as early as 1969 in commercial NMR instrumentation.¹ In the early 1970s, all research grade NMR instruments were interfaced to dedicated minicomputers which controlled simple pulse NMR data acquisition, as well as performed Fourier transform (FT) and standard post-FT processing. These systems incorporated analog oscilloscopes and plotters for output. By the mid-1970s, NMR instrumentation was designed

around minicomputers with 16–20 bit word length, and low-resolution color raster graphics and digital plotters began to appear.² In the early 1980s, dedicated NMR instrument computers began to be replaced by modern general design microcomputer and minicomputer systems, augmented by array processors.

The earliest reports of NMR laboratory computer networks predated general purpose workstation computers.^{3,4} Those networks were generally connected by several links, and were limited in functionality and speed. They had to contend with nonstandardized data formats, word lengths, and many other inconsistencies among the NMR instrumentation vendors. A few early implementations utilized higher speed parallel connections.^{3,4} The main purpose of the initial NMR laboratory networks was to move FT processing, display and plotting offline, away from the NMR instrument. A second important goal was centralized data archiving.

By 1990, virtually all NMR instruments were based on integrated graphics workstation computers. These NMR instruments also incorporated multiple microcomputers in various roles, ranging from control of sample temperature, to highly complex pulse and gradient sequence generation, to data acquisition and control of the user interface. Modern NMR data systems utilize intelligent digital plotters and intelligent subsystems for high-speed, high-resolution color graphics, in some cases also including three-dimensional graphics.

In modern NMR instrumentation, the computer is no longer isolated, but is instead generally networked to other computers and instrumentation in the laboratory and beyond. Laboratory computer networks belong to wide-area networks, including regional networks and the Internet. This was a natural outgrowth of the use in the late 1980s of graphics workstation computers, which from the beginning were network oriented.⁵

In NMR there are three largely separate arenas for computing:

1. Data acquisition and experiment control;
2. Data reduction; and
3. Data analysis and application.

In all modern NMR instrumentation, the tasks of acquiring data and controlling the spectrometer are fully covered by computers embedded in the instrumentation itself, usually through proprietary software which is not fully accessible to the user. Event timing in pulsed FT NMR is on a rapid and sustained timescale (events separated by 10^{-9} or more and sustained for minutes, hours, or days).

On the other hand, the NMR data reduction task has relatively light real-time constraints, although multidimensional NMR experiments can require very extended data reduction periods for larger datasets. Software provided by instrumentation vendors reduces the NMR spectral data to finished output and provides a broad range of standard and some specialized capabilities.

Today, many laboratories add local software routines or software systems provided from other laboratories or commercial sources, to augment the capabilities of software provided by the NMR instrumentation manufacturers. As a result of the almost ubiquitous use of UNIX computers and networking and UNIX-based networking in larger laboratories, the processing and analysis of NMR data has extensively migrated from the instrumentation computers themselves to auxiliary graphics workstations and networked computer servers. Even in smaller laboratories, PC-based data processing software can

2 DATA PROCESSING

add additional capabilities beyond that provided by the instrumentation manufacturers. The NMR manufacturers themselves also now offer data processing and analysis software for off-line application, utilizing workstations or PCs.

The trend to off-line NMR data reduction and processing began in the late 1970s, at that time for two reasons. First, NMR instrumentation computers of the period were not true multitasking computers and thus they were not capable of reliably collecting data and performing processing tasks simultaneously. Second, NMR spectrometer-based computers of the time were mostly manufactured specifically for the tasks of NMR data acquisition and these machines did not incorporate effective software development environments, including versatile program development tools (standard language compilers, symbolic debuggers, etc.), nor did many of these systems incorporate high-speed floating point capabilities necessary for many advanced algorithms.⁶

It is difficult to comprehend in the mid-1990s that NMR instrument computers of even 15 years ago might have program address space limitations and total memory storage that would today be greatly exceeded in a toy selling for less than US\$10. In fact, it is instructive to view the history of computers (Table 1) available to scientists over the past 30 years in order to gain perspective of the extraordinary changes that have taken place.

It is also instructive to look back at several figures that were prepared for a paper published in early 1988 on the changes in computer technology and their effect on the practice of chemistry.⁷ Figure 1 shows that the exponential relationships which were apparent from 1960s to the 1980s have indeed continued (at least thus far) and that the computer revolution in the laboratory remains on-track.

3 DATA PROCESSING IN NMR

3.1 Averaging and Early Implementations

Data processing gains more importance whenever there is noise. Since noise is generally uncorrelated, n successive additions of noise is only going to add as $\sqrt{n}$. However, the

Figure 1 Trends in laboratory computer technology: a surprising logarithmic trend

signal adds up linearly as n . Hence successive additions give rise to a signal-to-noise (S/N) ratio improvement of $\sqrt{n}$.

In the very early days of CW NMR, this averaging was performed through box-car integrators which were hardware.⁸ In this method there is very little room for further data processing, and what you got was what you had in the box-car integrators. With the introduction of microprocessors a new method was possible, whereby one could store the data and use it for a variety of purposes. This mode of data storage is essential for any useful data processing and has evolved a plethora of data-processing practices that are mostly borrowed or adopted from signal-processing techniques in electrical engineering. Although CW NMR had been routinely practicing signal averaging to enhance the S/N ratio of NMR signals, it was still limited by the time required to collect one scan of an NMR spectrum. This limitation is due to the constraints by the physical theory that dictates the rate at which the 'CW excitation' can be effected to obtain a reliable spectrum. This limitation was circumvented by the development of pulsed FT NMR. This began a new era of NMR which not only

opened a whole range of new experimental techniques, but also extensive data-processing techniques and practices.

3.2 FT Processing

The idea of FT NMR was brought to the attention of the NMR community by Lowe and Norberg.⁹ However, the development of the FFT algorithm by Cooley and Tukey¹⁰ enabled Ernst and Anderson¹¹ to extract the full potential of the method in acquiring NMR spectra with a higher S/N ratio per unit time.

In FT NMR, one acquires the NMR FID in the time domain that corresponds to one scan, and then those data are stored in a computer. The acquired analog signal is converted into a digital signal by using a high precision analog-to-digital converter (ADC), for the purposes of storing and further data processing. S/N ratio averaging is done in the time domain by repeatedly collecting FIDs and coadding the scans in the computer as they are stored. After a requisite amount of averaging is done, a fast FT (FFT) is performed to obtain the spectrum in the frequency domain.

FT NMR has brought with it a large number of data-processing techniques that enhance the appearance and quality of NMR spectra; it also has a few problems. Signal averaging in Fourier transform NMR spectrometers is necessarily preceded by converting the analog signal to digital form. This step involves various hardware and software considerations, which have been described in detail in the literature.^{12,13} We will touch on only some of the salient features. The FID is first 'sampled and held', before it is digitized. The number of bits in the digitizer crucially determines the 'dynamic range' and maximum allowable spectral width. The speed of digitization, coupled with Nyquist criteria puts a limit on the number of bits in the ADC. The number of bits in the ADC limits the ratio of maximum observable signal to minimum observable signal, i.e. the dynamic range. The difference between the word size of the computer and the size of the ADC limits the number of transients that can be averaged without altering or reducing the maximum dynamic range achievable by the ADC.

3.2.1 Quadrature Detection or Sign Discrimination

Among many aspects of NMR data processing which are intimately tied with the hardware and experimental practices, quadrature detection is one of the important considerations. In pulsed FT NMR spectroscopy, the frequency of the reading pulse (carrier frequency) determines the relative sign of frequencies in the NMR spectrum.^{14,15} If both real and imaginary components of the FID are simultaneously collected for each Nyquist time increment, then FT has to be performed on the complex FID in order to retain the sign information of the frequencies. This method requires that the spectrometer be equipped with two separate receiver channels whose gain and other characteristics are identical. One way to circumvent this difficult task is to use only one receiver channel, while collecting the real and imaginary components of the FID at successive instances of time incrementation, where the time incrementations are half of the value determined by the Nyquist criterion. This latter method involves two separate FIDs of the real and imaginary components, and

coadding them. Thus, it involves careful and consistent data representation and FT processing.

3.2.2 Window Functions

The signal-averaged time domain data can be Fourier transformed into frequency domain spectra. It has been found that multiplying the time averaged data with an appropriate function before the FT yields several advantages with respect to the 'apparent' resolution and sensitivity. An excellent account of this has been presented in the book by Ernst et al.¹⁴

The basic idea of these window functions is as follows.

1. Since, the true NMR signal is decaying in time, while the noise keeps a 'kind of constant amplitude', any decaying window function enhances sensitivity. If the decay of the applied function matches the decay of the true signal, it is called a 'matched filter'. Usually this is a simply decaying exponential, on the presumption that the FID is exponentially damped.
2. Any function that gives more weight to the later part of the FID is generally believed to enhance the resolution. The selection of the resolution enhancement function is, in general, intimately tied with assumptions about the lineshape. If one presumes a Lorentzian shape, with known widths, then a function which is exponentially increasing removes this shape and application of a decreasing Gaussian will result in a more resolved spectrum.
3. An unavoidable consequence of terminating the time domain acquisition after a certain time before the signal has completely decayed (truncation) is the appearance of ripples that are due to the well known 'Gibbs phenomenon'. An exhaustive analysis of several classes of function and their effect on Gibbs phenomenon has been carried out. In general, every function that reduces ripple broadens the spectrum, with the degree of broadening being roughly proportional to their efficacy in reducing the ripples.

A choice of a window function is made such that it would optimally increase sensitivity and resolution, while decreasing the ripple.

It is generally believed that one cannot simultaneously enhance both the resolution and sensitivity using window functions. A choice is made depending on the need and the nature of acquisition. If it is not possible to obtain a sufficient S/N ratio during the time domain acquisition, a matched filter can be used. If the data acquired have a sufficiently high S/N ratio, and if it is desired to improve the resolution, then a combination of resolution enhancement with ripple suppression is used. In this case, Ernst suggests a combination of Lorentz-Gauss apodization with a Hamming window.

It may be remembered that the window functions alter only the apparent resolution or sensitivity, but cannot replace the Utopian goal of achieving unlimited resolution and sensitivity at the acquisition stage. Another important aspect is that the application of window functions does alter the quantification of spectral parameters, such as intensities and linewidths, unless the window function chosen evaluates to unity at the origin.

3.2.3 Zero Filling

It has become common practice to extend artificially the acquired time domain data with zeros prior to the Fourier

transformation. The rationale behind this practice is that, since longer acquisitions improve resolution but nevertheless bring in data with a lower S/N ratio, it would be agreeable to achieve similar resolution without either wasting precious instrumental time in acquisition, or adding noise. Zero filling prior to FT is equivalent to interpolation of the spectrum (decimation of the time domain data) and thus gives better definition or representation of the lineshape. Zero filling once (adding as many zeros as the time domain data points) has been found to incorporate information from the dispersive component into the absorptive component, and hence it is useful to zero fill at least once. Adding more zeros than this extent serves merely to enhance the interpolative effects.

3.2.4 Phasing

The frequency domain spectrum is a mixture of absorptive and dispersive components which can be separated into their component parts. The absorptive and dispersive components correspond to the real and imaginary parts of the spectrum. It is possible to separate these two components in most of the one-dimensional NMR experiments. Many multidimensional NMR experiments are designed ('phase cycled') in such a way that this separation of absorptive and dispersive components is possible. Usually, the absorptive component has the advantage that the spectral lines appear narrower and that they are proportional to the number of spins and that they are symmetric, in contrast to the magnitude or power representations which would obviate the need for phase correction.

Phasing involves two levels of correction. The first level is called 'zeroth-order correction', where the task is to find a phase angle, θ for the whole spectrum such that it satisfies the following equations:

$$\begin{aligned} \text{New_Real_Part} &= \text{Old_Real_Part} \cdot \cos(\theta) \\ &\quad - \text{Old_Imaginary_Part} \cdot \sin(\theta) \quad (1) \end{aligned}$$

$$\begin{aligned} \text{New_Imaginary_Part} &= \text{Old_Real_Part} \cdot \sin(\theta) \\ &\quad + \text{Old_Imaginary_Part} \cdot \cos(\theta) \quad (2) \end{aligned}$$

and such that the area under the New_Real_Part is maximum, assuming an ideal baseline. In the first-order correction a similar phase angle θ is found, except that this phase angle varies linearly with the frequency.¹⁶

Several algorithms have been proposed for automating this phasing process. One such early attempt is that by Ernst,¹⁷ who tries to maximize the total area under the real part of the spectrum while minimizing the total area under the dispersive component. Another widely used algorithm is the DISPA algorithm, where the general principle is that (at least for a resolved line) the two-dimensional plot of well-phased real and imaginary parts is a circle for a Lorentzian line.¹⁸

3.2.5 Baseline Conditioning

Often, there are even or uneven distortions in the baseline of NMR spectra. A large portion of the uniform baseline distortions arise from dc offsets in the ADC and other hardware

sources. This distortion is usually corrected in the time domain by subtracting the complex average of the last 10% of the FID which has been acquired for a reasonable length of time. A number of factors (e.g. temporal effects and instabilities from instrumentation, and extremely broad peaks from known or unknown components of the sample) contribute to the uneven distortions, ridges, etc. Some of the uneven distortions can also be suppressed by deemphasizing the first few data points of the FID with an appropriate window function¹⁹ such as convolution difference.

3.2.6 Peak Analysis

To extract useful information from an NMR spectrum, it is necessary to perform peak analysis. This includes peak-picking, integration, analysis of linewidths and lineshapes, and assignment of spectral lines and their multiplet patterns. Integration can be carried out by using the simple trapezoidal rule, provided that there are no baseline distortions and when all peaks are well separated. In the more typical case, more elaborate methods are required to obtain accurate integrals for spectral peaks.

Analysis of spectral lines (frequencies and intensities) and their multiplet patterns has received considerable attention, especially for one-dimensional NMR spectra. Many programs have been written and tested to simulate one-dimensional NMR of simple spin systems. Two such programs that have become successful and widely used are LACON5²⁰ and DAVINS.²¹ These programs can be valuable tools in aiding and verifying assignments of simple one-dimensional spectra.

Analysis of spectral lineshapes and linewidths of one-dimensional NMR spectra is another area that has received considerable attention. These programs help in extracting a host of significant information regarding chemical exchange and other dynamic processes.^{22,23} Similarly, a large number of programs are available to extract relaxation parameters such as T_1 and T_2 .

It may be pointed out that most programs for spectral peak or multiplet simulation and extraction of dynamic or relaxation parameters suffer from various inadequacies of theoretical treatment, unless a complete treatment of strong coupling and relaxation effects is taken into account, as has been described in a recent paper.²⁴

3.2.7 Advanced Signal Analysis

As an alternative to the FT, a number of other techniques have become popular for transforming the time domain data into frequency domain spectra. Among these the linear prediction (LP), the maximum entropy method (MEM), the maximum likelihood method (MLM), and the least-squares (LS) or Bayesian methods are significant (see the review by Hoffman and Levy²⁵).

The LP methods presume that the future (past) time domain data can be represented as a linear combination of the past (future) time domain data. Whenever the FID is the sum of exponentially damped sinusoids and the S/N ratio is high, this assumption is valid. The advantage of the LP method is that it gives the spectral parameters (frequencies, linewidths, integrals, etc.) directly. Also, LP works well even when some of the early (immediately after the read pulse) time domain data points are missing, a case which results in baseline

distortions using FT processing. For this reason, the LP methods are also popular for predicting missing time domain points in multidimensional NMR spectra.

One significant disadvantage of LP methods is the computational inefficiency of the method. Most LP methods are based on singular value decomposition of the LP matrix created from, say, n time domain points. The method requires of the order of n^3 floating point operations, as compared with FFT which only requires $n \ln(n)$ floating point operations. But, whenever the total number of peaks is relatively small, the size of the LP matrices tends to be small. For this reason and because of operational constraints on acquisition times, LP methods are perceived to be useful in *in vivo* NMR spectroscopy. However, these spectra generally consist of nonexponential decays due to inhomogeneous samples and consequent broadening.

MEM methods derive their conceptual foundations from Shannon's information theoretic approaches. The basic idea in this approach is that, given some data and a set of possible models, the model is chosen so as to maximize the missing information content. In the NMR adopted version, the procedure is as follows:

1. A trial time domain pseudo-FID is generated.
2. A χ^2 statistic is calculated with an estimated variance, σ^2 , for the noise; then, for the correct model of the time domain data χ^2 should equal the number of data points.
3. An appropriate choice of entropy S is defined.
4. The trial time domain data are modified until S is maximized, while simultaneously satisfying the constraints on χ^2 [as described in (2)].

A recent account of MEM and its merits are described in the paper by Jones and Hore.²⁶

LS based methods presume a model for the number and characteristics of the NMR signals and minimize the square error between the model and the observed FID. Since very little is generally known about the number of signals, these methods are currently neither successful nor popular.

MLM,²⁷ as applied to NMR spectra, is quite similar to MEM. MLM purports to find the most likely model that would simultaneously improve resolution and sensitivity. The algorithm attempts to cast the FT in an iterative linear equation form and solves for the most likely model, while simultaneously subjecting it to either some weighting functions or some kind of χ^2 statistic constraints, in addition to performing miscellaneous corrections to the model at each iteration. The method has been shown to improve the contrast not only in one-dimensional NMR spectra but also in multidimensional NMR spectra.²⁸

An attractive feature of all the above methods is that, unlike FT, they do not suffer from Gibbs phenomenon (since they essentially attempt to 'fit' a model to the time domain data).²⁹ Most of the methods can be used such that they yield spectral parameters in a more direct form. However, unlike FT, they are computationally expensive, and almost computationally prohibitive for use on the largest data arrays in multidimensional NMR processing.

3.3 Data Processing in Multidimensional NMR

Multidimensional NMR data processing shares most of the conceptual features of one-dimensional processing, especially

with respect to the basic ideas of zero filling, windowing, FT and other techniques of converting the data into spectra. However, several additional features become important because of the large datasets and because of the idiosyncrasies of the experimental implementations used to determine the sign of frequencies in the remote dimensions. We will give an extremely brief overview of some of these features.

FT is the most common choice for initial conversion of multidimensional FIDs into spectra, for the most compelling reason of computational efficiency. However, in three-dimensional and higher multidimensional processing the time domain data cannot be collected with the required resolution in the remote dimensions due to an inordinate increase in the acquisition time. In such cases, it has been found that use of LP methods to predict more time domain data points in these remote dimensions prior to multidimensional FT is advantageous.

A consequence of the extremely large sizes of multidimensional time domain datasets is that FT cannot be carried out along all dimensions while holding the complete dataset in the random access memory (RAM) or its equivalent. It becomes necessary to store the data in mass storage media and then read or write the required portion repetitively. This also necessitates either transposition of the data for processing along remote dimensions, or evolving suitable modifications of the FFT algorithm to achieve the same goal. While the first choice increases the input/output time, the latter choice increases the complexity of programming.

Determining the sign of frequencies in the remote dimensions is another complexity of multidimensional NMR processing, which is intimately tied up with experimental procedures that are designed for the same purpose. Two conceptually important experimental methods have been evolved for this purpose. The first is called the States-Haberkorn (SHR)³⁰ method in which both the real and imaginary parts of the remote dimensional time domain data are acquired for the same length of the remote time evolution, similar to the two-receiver-channel detection in one-dimensional NMR. The second method, time proportional phase incrementation (TPPI),³¹ achieves the same purpose by modifying the phase cycling of the pulse sequence used, similar to the one-receiver-channel detection in one-dimensional NMR. There are many variations of these two basic procedures. Thus it becomes necessary to keep track of the data ordering, representation, and storage method of the real and imaginary components of every dimension in the multidimensional FID, along with the basic scheme used to discriminate the sign of frequencies in the remote dimension. Furthermore, FT processing has to be consistent with the data representation.

Most concepts regarding one-dimensional data processing are also applicable in multidimensional processing. In the case of applying window functions, some new functions have become popular. One of these is the shifted or unshifted sine-bell window³² and has been found to be useful for phase sensitive spectra, particularly those with antiphased cross peaks. For spectra with inphase cross peaks other resolution enhancing windows are more useful. Caution has to be exercised for quantification purposes, since integrals are unchanged only for window functions that evaluate to unity at the origin. Thus, use of an unshifted sine-bell for quantifying a NOESY spectrum is inappropriate. Some effort has been directed towards automation of peak picking, which would be

Figure 2 Stacked views of the small subregion (base-1') of a 500-MHz 24-mer RNA hairpin-loop spectrum. (a–c) Based on 1000×1000 data; (d–f) zero filled to 4000×4000 total real data. (a and d) Processed conventionally; (b and e) processed using maximum-likelihood method (MLM); (c and f) processed using MLM and symmetrization

an important advantage for multidimensional spectra that may contain thousands of cross peaks.

Baseline distortions and ridges contribute to difficulties in peak identification and quantification. Considerable effort has been expended to obviate this problem. An example of automated removal of these artifacts is shown in Figure 2.³³ Use of MLM to obtain contrast enhancement of peaks from artifacts has also proved useful for peak identification, and the quantification of integrals in such spectra seems to be reliable (Figure 3).³⁴

3.4 Automated Analysis of NMR Spectra

As a result of the dramatic growth of new multidimensional NMR techniques, and through concomitant growth of data processing tools (both software and hardware), there is increased interest, need, and demand to automate the study of more and more complex molecules. A critical step in the study of complex molecules, after obtaining the NMR spectral data, is to make resonance assignments. Notable developments in artificial intelligence (AI) methods have

added impetus to the need for automation of this process. One area in which there is some hope is in the analysis of ^{13}C NMR spectra of reasonably large organic molecules.³⁵ Considerable effort has also been directed to easing the process of assignment by using computers. Some effort, with moderate success, has been expended in the following components of the assignment process. Programs have been written either merely to perform book-keeping tasks or to aid the manual assignment process graphically.^{36–38} Use has been made of symmetry based algorithms to identify weakly coupled well resolved multiplet patterns.³⁹ Feed-forward three-layer neural networks with back-propagation training have also been used to identify AX type antiphase cross peaks.^{40,41} Similar network architecture has been used to sieve out, with modest success, authentic peaks from spectral artifacts in a NOESY spectrum.⁴²

Some methods have been suggested that demonstrate progress towards the automation of the biomolecular NMR spectral assignment methods.⁴³ Use of neural networks seems to be especially promising in this direction.^{44,45}

Figure 3 (a) Original spectrum prior to baseplane correction, where a small section (512×512 data size) of a two-dimensional experimental NOE spectrum was combined with a synthetic dataset having resonance peaks and baseplane distortion. (b) Stacked plot of baseplane information filled with two-dimensional nonlinear weighted interpolation (the filling lines in the F_2 direction only are shown). (c) Refined baseplane obtained by multiplication in the time domain by a two-dimensional shifted Gaussian window function that was generated automatically by a program. (d) Corrected spectrum that was obtained by subtracting the refined baseplane (c) from the original spectrum (a)

4 MOLECULAR MODELING

NMR has become an important, if not essential, tool for the determination of the solution structure of macromolecules. The procedure for structure determination usually proceeds in three steps: (1) several NMR experiments, (2) conversion of information obtained from the NMR experiment into structural information, and (3) structure determination based on the NMR and holonomic information. Steps (2) and (3) can also be combined. There are recent approaches which use NMR parameters directly in the refinement procedure.

Initial molecular structure determinations relied on one-dimensional NOE experiments in which the change in intensity of NMR signals was monitored when neighboring spins were irradiated. The resultant intensity change is proportional to the inverse sixth power of the distance between the two protons under study, since the dominant relaxation mechanism is due to magnetic dipole coupling.^{46,47} With the advent of two-dimensional NMR experiments, information can be obtained about the structure of much larger and more complex molecules.⁴⁸

Typically, two types of structural information can be obtained from NMR experiments: (1) distance information from proton–proton NOESY and/or ROESY spectra; and (2) angular information based on COSY-type (or scalar coupling based NMR) experiments. Angular information is usually supplementary to NMR-derived distances due to the lack of accuracy with which J values can be obtained, and sometimes limitations in its conversion to dihedral angles. A more detailed discussion of two-dimensional NMR experiments is presented by R. R. Ernst (see *Multidimensional Spectroscopy: Concepts*).

The NOESY experiment has proven to be a challenge in the conversion of NOE intensities to distances. The problem lies in

the fact that the cross peak intensities are not only dependent on the distance between protons, but also on the motions of the molecule. In addition, in the case of large molecules, ‘spin diffusion’ (the indirect transfer of magnetization between protons), contributes to the intensity of the cross peaks.⁴⁹ The procedures for determining distances from NOE intensities can be divided into qualitative and quantitative solutions. The latter follow two different approaches: (1) (hybrid) relaxation matrix analysis,^{50,51} and (2) gradient-based analysis.^{52,53} The gradient-based method involves the analysis of cross peak intensities in a refinement procedure and will therefore be described after the discussion of refinement methods.

The qualitative approach for determining NOE-derived distances is based on the isolated spin pair approximation (ISPA) in which the internuclear distance is estimated by referencing the intensity and the distance to two protons of known distance. This technique can be used for short mixing times and short correlation times, but under conditions where spin diffusion is a factor this method will underestimate the distance if the distance being measured is larger than the reference distance (the usual case) and overestimate the distance if the distance is smaller than the reference distance.⁵⁴ Similarly, when a distance range is needed for structure determination techniques, such as in distance geometry (DG) or molecular dynamics (MD) calculations, the range is estimated from the strength of the intensity of the cross peak at different mixing times.

Relaxation matrix approaches give a more quantitative measurement of the distance between protons by taking into account the whole network of spin systems. This technique solves the relaxation matrix to interpret distances, and this is thus referred to as a DIRECT method.^{50,55} The problem with this approach is that, in order to solve the relaxation matrix, most of the cross peaks and diagonal peaks have to be resolved

or else the relaxation pathway is not well established.⁵⁶ This method is efficient with small molecules, where the S/N ratio is high and where there is minimal overlap of peaks in the NOESY spectrum.

A solution to the incomplete relaxation matrix involves techniques that combine experimental intensities with those calculated based on a starting structure. Iterative relaxation matrix analysis (IRMA) is an iterative program that combines relaxation matrix calculation with restrained molecular dynamics (r-MD). The program starts with available experimental NMR intensities plus a starting structure, from which it then calculates the missing intensities. With this hybrid of both experimental and calculated intensities it solves the relaxation matrix to produce distances.^{51,57} These distances are then used in r-MD or distance geometry calculations to produce a new starting structure for IRMA that is more defined by the experimental intensities than the initial starting structure. This cycle is repeated until a final structure is produced which optimally fits the experimental spectra.

MARDIGRAS (matrix analysis of rates for dIscerning geometry in solution) is a similar technique, developed by James et al.^{58,59} which generates an augmented intensity matrix. This intensity matrix, which contains all the scaled experimental intensities and the calculated intensities of the starting structure, is then solved for the distances. This technique differs from IRMA in that it does not require a restrained molecular dynamics or restrained distance geometry step, but instead requires internal consistency in the relaxation matrix. This makes MARDIGRAS less time-consuming.

CAMELSPIN/ROESY experiments, like NOESY data, provide information about the distance between protons, but there are different problems associated with ROESY, such as off-resonance and TOCSY/HOHAHA effects. The program CROSREL, developed by Leeflang and Kroon-Batenburg,⁶⁰ is able to accept either ROESY or NOESY cross peak intensities as input to solve a full relaxation matrix. This program takes into account spin diffusion, internal motions and anisotropic effects; for the ROESY experiments it accounts for nonrelaxation factors, such as HOHAHA effects. A three-dimensional version of the recently developed LOUSY can unambiguously yield 'ROE-only' effects, by separating HOHAHA/TOCSY effects.

The process of determining the structure of a molecule depends on computational programs that globally search conformational space to find a set of molecular structures consistent with both experimental and holonomic constraints of bond lengths, bond angles, and steric limitations. Distance geometry, a branch of mathematics,⁶¹ is routinely used to determine initial structures of proteins which can then be refined further by means of restrained molecular dynamics calculations. An advantage of distance geometry is that it is able to explore conformational space in a relatively short period of time.⁶² The structures produced will fit well with the distance constraints applied, but will have high potential energy due to close nonbonded contacts, which are alleviated in the molecular mechanics step. There are two general methods of distance geometry: (1) the matrix method,^{63–66} and (2) the variable target function in dihedral angle space technique.^{67,68} In the former, distances between points are converted into coordinates by a procedure called embedding. The coordinates are then optimized against an 'error function' which increases rapidly when the distance constraints are

violated. The first solution structure of a protein, proteinase inhibitor IIA from bull seminal plasma (BUSI IIA), was determined in this manner with the program DISGEO in 1985 by Williamson et al.⁶⁹ The variable target function approach first randomizes the dihedral angles around single bonds and then proceeds to adjust the conformation to fit a set of experimental constraints, by varying the dihedral angle. The first program to implement this technique was DISMAN, developed by Braun and Go.⁶⁷ The current program that is based on this technology is DIANA, which was developed by Wüthrich's group. This new version includes vectorization to reduce the amount of central processing unit (CPU) time.

Another approach used for structure determination, often used in conjunction with distance geometry, is restrained molecular dynamics,^{70,71} where the energy of the system is minimized as the structure is allowed to explore conformational space, along with experimental NOE constraints. The molecular dynamics programs most widely used are GRO-MOS (Groninger molecular simulation),⁷² AMBER 4.0,⁷³ X-PLOR,⁷⁴ and CHARMM.⁷⁵ Each molecular dynamics simulation program has a force field which consists of a Lennard-Jones potential, a Coulombic interaction, a dihedral potential, and harmonic potential terms that constrain bond lengths, bond angles, and torsion angles; for restrained molecular dynamics an energy potential is included for the NMR constraints. The form of the last potential depends on the user, but usually takes the form of a flat-well potential, where the estimated experimental error can be incorporated as the width of the flat well.^{76,77} Restrained molecular dynamics has also found success in the structure determination of nucleic acids, where the choice of initial structure is not usually a problem.

Simulated annealing is widely used for biomacromolecular structure. The goal of molecular dynamics calculations is to find the global minimum in a potential energy surface, containing multiple local minima. In the simulated annealing protocol, the temperature of the system is elevated so that the simulated molecule can overcome energy barriers, and this is followed by slow cooling which will enable the lowest energy form to be achieved.⁷⁸

A relatively new implementation of an old concern is the use of time-averaged distance constraints in molecular dynamics calculations. In the calculations mentioned above it has been assumed that the NOE reflects a static distance, but in reality it reflects a time-averaged distance. A more realistic approach would be to replace the instantaneous distance r in the NOE-pseudo-potential energy term with the time-averaged distance $\langle r \rangle$, where:

$$\langle r \rangle \cong \langle r(t)^{-6} \rangle^{-1/6} \quad (3)$$

Usually since the NOE is assumed to be predominantly due to dipolar interactions the intensity of the NOE cross peaks are proportional to r^{-6} . But the timescale of the molecular dynamics simulation is short compared with the correlation time for the molecular tumbling of the molecule, so the influence of angular fluctuation can be ignored. The additional term involving t is a memory function so that $\langle r \rangle$ is a running average, with the recent history having more weight than past history.^{79,80} Theoretical comparison studies of standard and time-averaged refinement methods have been done on the DNA hexamer d(GAATTC)₂⁸¹ and on the macrocyclic immunosuppressive agent FK506.⁸² For both studies, the

two methods gave similar gross structures, but the time-averaged method gave a superior picture of the fine structure and the inherent flexibility of the molecule. This technique has also been used in the refinement of the DNA octamer [d(GTATAATG)]·[d(CATATTAC)]⁸³ and tendamistat⁸⁴ using experimental NOE-derived distances. The results of these studies confirm the theoretical results, in that the time-averaged protocol gave a more realistic picture of the flexibility of the molecules. In addition, the time-averaged structure compared with the standard refinement structure gave better agreement with the experimental data. Torda et al.⁸⁵ have recently applied this technique using J coupling constant information. A penalty function was added to the force field which allowed the J coupling information to be enforced as a time-averaged quantity. The results were similar to those for the distance time-averaged constraints, i.e. a greater ability to enforce experimental restraints while exploring a larger region of conformational space.

Yip and Case⁵² and Baleja et al.⁵³ pioneered the gradient-based analysis of NOE intensities in a refinement protocol. This involves incorporation into the force field of a penalty function based on the NOE intensities in which the experimental intensities are compared with NOE intensities calculated using a full relaxation matrix analysis based on the starting model. This method not only takes into account spin diffusion, but also differential motion within the molecule. A gradient of the NOE intensities with respect to structural parameters, such as the Cartesian coordinates, is calculated. This can be done in three ways: (1) by manipulation of the matrix exponential expression, e.g.⁸⁶

$$\frac{\delta}{\delta R_{k,l}} A(\tau)_{i,j} = \sum_{r,u} L_{r_i} L_{r_k} L_{u_l} L_{u_j} \times \left[\frac{\exp(-\lambda_r \tau) - \exp(-\lambda_u \tau)}{\lambda_r - \lambda_u} \right] \quad (4)$$

where L and λ are eigenvectors and eigenvalue matrices of R , respectively, and $A(\tau)$ represents the NOEs between protons i and j ; (2) by numerical integration of $d(a)/dt = -(R)(a)$ by Gear's algorithm; and (3) approximation of (a) based on the Taylor expansion series.⁸⁷ Determining the gradient of the intensities can be computationally exhausting in terms of time and memory, especially for method (1). It is possible to shorten the time of computation while still maintaining the accuracy of the calculation by evaluating the force of the NOE potential in the first steps and subsequently in every X steps during the molecular mechanics run, or when the proton moves more than x nanometers away. Also, instead of calculating the relaxation matrix for the whole molecule, sets of overlapping submolecules can be created so that cross peaks influence only nearby spins, and not the whole molecule. The advantage that this technique has over others is that the correlation times, in addition to the nuclear coordinates, can be altered to minimize the penalty function.

Heuristic refinement,⁸⁸ another refinement technique for proteins, is based on a systematic search of conformational space, but it uses prior knowledge of the system under study, thereby making it less computationally demanding. PROTEAN⁸⁹⁻⁹¹ is a program based on this theory for the structure determination of proteins. The protocol used is: (1) to define the secondary structure from NMR data plus

a knowledge of the protein sequence; (2) to determine the coarse topology of the folded structure by coarse systematic sampling of conformational space; and (3) to define the spatial distribution of atomic positions.

1 INTRODUCTION

High resolution NMR spectroscopy is one of the most powerful tools available for chemical structure elucidation. The great majority of high resolution NMR experiments are carried out on more or less pure materials, in which the signals of a single species dominate. NMR has until recently been much less widely used in the study of mixtures, but two techniques are changing this. The first is HPLC-NMR, in which NMR experiments are performed directly on the eluent stream from a chromatography column, in either continuous- or stopped-flow mode. HPLC-NMR is capable of handling complex mixtures, and offers great flexibility through the use of different stationary and mobile phases, but requires special hardware and is expensive both in instrument time and in solvent consumption. In the second, diffusion-ordered spectroscopy (DOSY), the results of pulsed field gradient spin echo experiments are analyzed to determine diffusion coefficients for the individual signals in a spectrum, and hence to distinguish between the signals of different components in a mixture. In most applications, two- or three-dimensional spectra are synthesized in which signals are dispersed in one dimension according to their diffusion coefficients. DOSY uses standard spectrometer hardware and sample handling, requiring only the additional software for data analysis and spectrum synthesis; the field has been authoritatively reviewed by Johnson.¹

DOSY and HPLC-NMR may be viewed as analogues, DOSY effecting a virtual separation as opposed to the true physical separation used by HPLC. The versatility that changes in stationary and mobile phase afford when separating substances by HPLC is to some extent paralleled by the possibility of manipulating the relative diffusion coefficients of different species by changing solvent, or by adding agents to bind species preferentially. The two techniques are largely complementary, HPLC-NMR generally being the more powerful but slower and more expensive technique. In principle it

would be possible to achieve higher resolution by combining stopped-flow HPLC-NMR with DOSY than either technique can provide in isolation.

Figures 1 and 2 illustrate some of the basic principles of DOSY. A series of measurements is made of pulsed field gradient stimulated echo spectra (Figure 1), in which diffusion causes signals to be attenuated. Fitting the signal peak heights as a function of gradient pulse area to the theoretical Gaussian form allows a diffusion coefficient and a standard error to be calculated for each peak in the spectrum. A two-dimensional diffusion-ordered spectrum can then be synthesized (Figure 2) in which the normal spectrum (top) is used to determine the horizontal (chemical shift) domain lineshape for each peak, and the diffusion coefficient and standard error are used to define the position and width of a Gaussian lineshape in the vertical (diffusion) domain. All signals for a given molecule should then appear in a horizontal line, at the same diffusion coefficient D ; cross-sections through the 2D spectrum at different values of D then separated subspectra for the different species in a mixture. This simple and effective approach is however restricted to the high resolution case where peaks are well-resolved in the chemical shift domain: where signals overlap in the normal spectrum, analysis can be much more problematic.

The name DOSY deliberately invites comparison with 2D NMR methods such as COSY (correlation spectroscopy) and NOESY (nuclear Overhauser effect spectroscopy). There is however an important distinction to be drawn between the true 2D techniques, in which the positions of signals in the indirectly detected frequency domain (F_1) are encoded as frequencies of amplitude or phase oscillation as a function of the evolution time t_1 , and DOSY, in which the positions of signals in the diffusion domain must be determined from the rate with which signal amplitude decreases as the strength of the applied magnetic field gradients is increased. F_1 frequencies in COSY etc. may be straightforwardly and unambiguously obtained by Fourier transformation of the signal oscillations as a function of t_1 (as well as by more sophisticated techniques such as linear prediction, maximum entropy or the filter diagonalization method), but there is no such general way to invert the corresponding experimental data in DOSY experiments. The Fourier transform is highly effective at unraveling superimposed oscillations, which may be treated as complex exponentials, but unfortunately the corresponding method for superimposed real exponential decays, the inverse Laplace transform, is numerically intractable.

DOSY therefore is forced to rely on simplifying approximations when attempting to interpret signal decay in terms of diffusion. By far the most common approximation is to assume, as in Figure 2 above, that each signal originates from a single species; this can allow very accurate estimation of diffusion coefficient, but risks misleading the experimenter if a given signal actually contains contributions from more than one species. Where two signals with different diffusion coefficients overlap, fitting the data to the form expected for a single decay will yield a compromise diffusion coefficient intermediate between the two true values. It seems unlikely that a practical, general solution will be found to the problem of unambiguously inverting an experimental decay of signal amplitude with gradient pulse area into an accurate distribution of signal strength as a function of diffusion coefficient, but a number of useful approximations are available.

Figure 1 500 MHz ^1H pulsed field gradient spin echo spectra for a mixture of acetone (A), choline (C) and DSS (2,2-dimethyl-2-silapentane-5-sulfonate sodium salt, D) in D_2O ; a signal is also seen for residual HDO (W). 30 spectra were acquired using the PFGLED sequence of Figure 3(b) using gradient strengths incremented linearly from 0.5 to 15 G cm^{-1}

Figure 2 DOSY spectrum calculated from the data of Figure 1

DOSY is, in essence, nothing more than a new form of data presentation applied to a much older family of techniques, that of pulsed field gradient measurements of diffusion coefficient. However, by highlighting the use of such methods for the analysis of mixtures and focusing attention on some of their limitations, DOSY has led both to significant improvements in techniques for diffusion measurement and to a much wider range of applications.

2 HISTORICAL BACKGROUND

It was recognized very early in the development of NMR that diffusion contributes to the attenuation of spin echo

signals when experiments are performed in an inhomogeneous magnetic field. Spins that move through a spatially-varying magnetic field during a spin echo experiment will suffer changes in Larmor frequency, leading to changes in signal phase that depend on the motion undergone. Diffusive motion will lead to a distribution of different signal phases, and hence to a diminution in net signal. This principle has been extensively exploited, and NMR remains one of the most widely-used of techniques for measuring diffusion.^{2,3}

Experiments carried out using a static field which remains inhomogeneous throughout are limited in application, as the line broadening caused by the field inhomogeneity leads to signal overlap and reduces signal-to-noise ratio. The introduction

of pulsed magnetic field gradients allowed spin echo signals to be measured under high resolution conditions, retaining high sensitivity and allowing signals with different Larmor frequencies to be distinguished. Pulsed field gradient spin echo experiments come in a variety of forms, but all share the same basic features. After initial excitation, the evolution of the spins falls into three distinct phases: a defocusing period, in which field gradient pulses are used to give each spin a position-dependent phase; a delay, during which diffusion takes place; and a refocusing period, in which gradient pulses are applied to reverse the original phase encoding. For a single rectangular field gradient pulse of width δ and amplitude G , the extent of defocusing or refocusing produced is described by the gradient pulse area $q = \gamma\delta G$; an effective gradient pulse area may be defined for more complex sequences of gradient pulses. Spins that experience no net movement during the diffusion period refocus exactly, but where diffusion takes place, a distribution of signal phases results and the net magnetization is therefore attenuated. The net signal attenuation as a result of unrestricted diffusion shows a Gaussian dependence on q (an exponential dependence on q^2):

$$S(q) = S(0) \exp[-D \Delta' q^2] \quad (1)$$

where D is the diffusion coefficient, and the effective diffusion time Δ' is the time Δ between the midpoints of the defocusing and refocusing periods less a small correction for diffusion during the gradient pulses. It is important to choose values for q^2 that give an accurate record of diffusional attenuation for all species of interest, without wasting time acquiring spectra which are uninformative.¹

The idea that pulsed field gradient echo spectra could be used for the analysis of mixtures dates back at least to the 1981 work of Stilbs,⁴ but the concept of a diffusion-ordered spectrum was only introduced by Johnson in 1992.⁵ Two distinct strands may be distinguished in the development of DOSY: high resolution DOSY, in which relatively complex mixtures can be analyzed with good diffusion accuracy using well-resolved spectra where the majority of peaks arise from a single species, and low resolution DOSY, in which the overlap or complete superimposition of signals limits the reconstruction of the diffusion dimension of the DOSY spectrum to a relatively low resolution. Between these two poles a variety of approaches may be used to constrain the analysis in order to maximize the amount of chemically useful information to be obtained from the experimental data.

3 DATA ANALYSIS

3.1 High Resolution DOSY

The simplest approach to analyzing the results of DOSY experiments is to assume that each individual peak in the NMR spectrum arises from a single species, and hence has an amplitude which varies with gradient pulse area according to equation (1). In simple mixtures with well-resolved signals this is straightforward, and gives the maximum interpretable information for a minimum of effort. The basic data processing follows the pattern described briefly in the Introduction. After measurement, experimental free induction decays are weighted and Fourier transformed as normal; where most signals have

the same common linewidth, mild resolution enhancement may be useful. Careful baseline correction is then carried out, to minimize distortions of the diffusion spectrum caused by instrumental shortcomings and crosstalk between signals. Peak heights are tabulated as a function of gradient pulse area for each peak identified in the spectrum, and two-parameter exponential least squares fitting as a function of q^2 is carried out. This yields an apparent diffusion coefficient and a standard error for each peak, which may then be used in synthesizing a DOSY spectrum. For each peak j in the normal spectrum (for convenience, the spectrum with lowest q is generally used) a two-dimensional peak is constructed which has the same shape in the NMR dimension as that $S_j(F)$ in the normal spectrum, a volume proportional to the peak height in the normal spectrum, and a Gaussian shape in the diffusion dimension which is centered on the fitted diffusion coefficient D_j and has a width determined by the standard error σ_j . The final 2D DOSY spectrum is then the sum of N such 2D peaks:

$$S(D, F) = \sum_{j=1}^N \frac{S_j(F)}{\sqrt{2\pi}\sigma_j} \exp\left[-\frac{(D - D_j)^2}{2\sigma_j^2}\right] \quad (2)$$

Several refinements of this basic approach are possible. Even the best available spectrometer hardware is unable to switch as rapidly as required between a field gradient pulse and high resolution conditions, with the result that spectra show small distortions because of the slow recovery of the main magnetic field B_0 to maximum homogeneity. These distortions may be corrected by reference deconvolution⁶ (qv) if there is a suitable reference signal available in the spectrum. To the normal requirement that the reference signal should be a strong, well-resolved singlet, must be added the stipulation that the reference material should preferably diffuse no more rapidly than the slowest of the species under study, so that the reference signal remains strong in all the experimental spectra. One candidate for such a material in non-polar solvents is polydimethylsiloxane. In practice, 2–3 fold improvements in diffusion resolution may readily be obtained using reference deconvolution.

Another common instrumental shortcoming that reduces resolution in the diffusion domain of a DOSY spectrum is non-uniformity of the pulsed linear field gradient, i.e., the presence of gradients of higher orders than one. Variations of 10% across the active volume of the probe are common, with larger discrepancies outside the observe coil. The effect of such variation is make the signal attenuation dependence on q deviate from a Gaussian: effectively the decay becomes the sum of different Gaussians from different regions of the sample. For signals that are only mildly attenuated this is of little consequence: relatively clean Gaussian behavior is seen, corresponding to a gradient strength averaged over the sample. Where, however, signals undergo severe attenuation, the weaker gradient in some parts of the sample leads to significantly stronger signals than expected at high nominal gradient strengths. These deviations from Gaussian behavior lead to an increased error in the fitting process, and are one of the causes of the common observation that DOSY signals are broader in the diffusion domain at high diffusion coefficient. The loss of resolution can be reduced by empirically adjusting the apparent values of q^2 to force the experimental signal decay to adopt the expected Gaussian shape: this improves

the accuracy of fit, and hence the accuracy with which relative diffusion coefficients are determined, at the expense of a small loss in absolute accuracy. A much more effective solution, however, is to determine the form of the distribution of signal strength as a function of gradient strength, and then use this information to calculate the predicted form of the signal attenuation curve as a function of q^2 . This may conveniently be done by mapping the experimental distributions of signal strength and gradient strength as functions of position within the sample, and then integrating over the sample to find the overall signal attenuation curve. Fitting to this function, which may conveniently be represented as the exponential of a power series, rather than to a Gaussian, then gives much better statistics for signals that experience strong attenuation. The benefits are particularly apparent when studying mixtures with a wide range of diffusion coefficients, since at high q the signal intensities of rapidly diffusing species will be dominated by contributions from the regions of the samples experiencing the lowest gradients.

Data processing strategies in DOSY depend on the nature of the sample, the characteristics of the spectrum, and the signal-to-noise ratio of the NMR data. Where resolution is good but signal-to-noise ratio poor, as for example with ^{13}C or ^{29}Si , there is little need for baseline correction and little advantage in using reference deconvolution. Conversely, for ^1H systems with very high signal-to-noise ratios, baseline correction is important and the improvement in diffusion resolution obtainable by combining reference deconvolution and gradient mapping can approach an order of magnitude.

3.2 Low Resolution DOSY

The problem of identifying an arbitrary distribution of signal intensity as a function of diffusion coefficient (a "diffusion spectrum") from measurements of signal attenuation as a function of gradient pulse area is one that has already been intensively studied in a different context, that of dynamic light scattering. Given the absence of a method for computing accurate inverse Laplace transforms from experimental data, the challenge is to use suitable approximations, constraints and prior knowledge to enable realistic diffusion spectra to be constructed. For polydisperse systems, where there is a continuous distribution of diffusion coefficients, only very general constraints can be applied, typically that the diffusion spectrum remain positive and that it be as simple and featureless as is compatible with the experimental data. This conservative approach minimizes the risk of misinterpretation, but yields large uncertainties in the diffusion coefficients of any monodisperse components in a mixture. The two approaches that have proved most successful in DOSY analysis of polydisperse systems are CONTIN⁷ and maximum entropy.⁸

3.3 Intermediate Approximations

Many mixture analysis problems lie between the two extremes of a fully-resolved and an unresolved NMR spectrum. Some spectral lines are well-resolved, others are the sum of two or more components, which may be partially resolved. Under such circumstances low resolution DOSY has little to offer unless the system exhibits only a few diffusion coefficients which are of very different magnitudes. The straightforward monoexponential analysis as a function

of q^2 described above is more successful in providing useful chemical information, since where two signals with different diffusion coefficients contribute to a given peak the apparent diffusion coefficient will be intermediate between the two values. Since the effects of overlap are simple where only two signals are involved, DOSY spectra with a minority of signals overlapping are relatively straightforward to interpret, but the ability to extract a complete subspectrum for a given diffusion coefficient is lost.

Between the Procrustes bed of a single exponential fit and the open-ended analyses of CONTIN and maximum entropy lie a range of methods designed to fit the experimental data to more or less constrained models, using prior knowledge of the likely form of the diffusion spectrum to allow the maximum of useful information to be extracted from the experimental data. In moderately crowded spectra the majority of cases of overlap will only involve two signals, so a logical first step is to replace monoexponential fitting with biexponential. Simple four parameter biexponential fitting can be quite satisfactory provided that the two diffusion coefficients differ by a factor of two or more, but the generation of initial guesses for the iterative fitting risks introducing bias. A safer solution is the general package for multiexponential fitting SPLMOD (SPLine Model), which has been used successfully⁹ for DOSY by incorporating pragmatic rules for the rejection of spurious fits. A variety of more sophisticated approaches to analyzing multiple overlapping exponentially decaying spectra have been proposed, including the DECRA (direct exponential curve resolution algorithm),¹⁰ MCR (multivariate curve resolution)¹¹ and CORE (component resolved NMR)¹² methods, but have yet to be widely applied.

4 EXPERIMENTAL METHODS

4.1 Homonuclear 2D DOSY

The earliest experiments used the basic Carr-Purcell pulse sequence in the presence of a continuous field gradient. The introduction of pulsed field gradients has already been mentioned; the next improvement was the shift to using a stimulated $(90 - \tau - 90 - \Delta - 90 - \tau)$ rather than a Carr-Purcell $(90 - \tau - 180 - \tau)$ echo sequence. This carries a factor of two penalty in sensitivity, since on average only half of the initial transverse magnetization is refocused in a stimulated echo, but minimizes the time for which the magnetization remains transverse. This is of value for systems where T_2 is significantly shorter than T_1 , but is particularly useful for systems with homonuclear scalar coupling. Restricting the time that magnetization spends in the transverse plane minimizes the impact of J modulation, and hence avoids the introduction of multiplet phase errors. Since high resolution DOSY generally relies on peak heights as a guide to signal intensity, any dispersion mode character to the experimental lineshape greatly increases the risk of signal overlap, and hence of crosstalk between adjacent peak heights and distortion of the diffusion spectrum.

The parent pulse sequence for most DOSY experiments is the pulsed field gradient stimulated echo (PFGSTE) sequence of Figure 3(a), in which the delays τ are just long enough to encompass the transmitter pulse fall time, the width δ of the gradient pulse, and the recovery time for the gradient pulse.

Figure 3 Radiofrequency (RF) and gradient (G) pulse sequences for DOSY: (a) pulsed field gradient stimulated echo (PFGSTE); (b) pulsed field gradient longitudinal echo delay (PFGLED); (c) gradient compensated stimulated echo sequence (GCSTE); (d) bipolar pulse pair stimulated echo (BPPSTE); (e) one-shot BPPSTE; (f) convection compensated double stimulated echo. 90° pulses are indicated by narrow rectangles in the RF traces and 180° by broad. Purge/homospoil pulses as an alternative or adjunct to phase cycling are indicated with dotted lines; up/down arrows indicate gradient pulse amplitudes that are increased/decreased to obtain increased diffusional weighting of signals. In the defocusing and refocusing periods, the spacing between RF pulses is given by the sum of the gradient pulse width δ and the gradient recovery delay τ_R , as shown for sequence (a)

If the diffusion delay Δ is defined as the time between the midpoints of the two gradient pulses, the correction to the diffusion time for diffusion during the gradient pulses is $-\delta/3$, giving $\Delta' = \Delta - \delta/3$ and the familiar attenuation expression

$$S(q) = S(0) \exp[-Dq^2(\Delta - \delta/3)] \quad (3)$$

This basic sequence is perfectly serviceable for many purposes, but is capable of considerable improvement. Two problems which are of particular importance under high resolution NMR conditions are those of slow main field recovery from the gradient pulses, causing distortion of the early part of the free induction decay, and interference with the deuterium field frequency lock. In general the former effect is brief, giving a broad distorted base to lines, and the latter relatively long-lived, giving sharp but “unphaseable” lineshapes.

The problem of main field disturbance, usually due to eddy currents induced in the probe and magnet metalwork, is much less severe in modern instruments, which have self-shielded (“actively shielded”) gradient coils. These minimize magnetic flux leakage outside the gradient coil, and hence give rise to much weaker eddy currents. For probes with unshielded gradient coils, a very effective way to circumvent problems from eddy currents is to add a z-filter to the stimulated echo sequence, storing the refocused magnetization for some tens of ms until the field is stable. Such a LED (longitudinal echo delay)¹³ step may be included in a variety of DOSY pulse sequences; the simplest is the PFGLED sequence of Figure 3(b).

A more general solution to the problem of eddy currents in modern high resolution spectrometers, which also deals with the problem of gradient pulses suppressing the deuterium lock signal and hence introducing slow B_0 shifts, is to use bipolar pairs of field gradient pulses. Using closely-spaced matched pairs of gradient pulses of opposite polarity cancels eddy current effects to first order, and refocuses the deuterium lock signal in a gradient echo. Such opposed pulse pairs may have one partner outside the defocusing/refocusing periods, or have both pulses within the defocusing/refocusing period but bracketing a 180° radiofrequency pulse. Sequences using the latter construct are generally referred to as bipolar sequences, since the diffusion encoding is carried out by the bipolar pulse pair; such sequences have a number of advantages. In second-order scalar coupled systems, relaxation effects can lead to zero quantum coherence causing phase errors in simple stimulated echo pulse sequences; by refocusing chemical shifts, bipolar sequences avoid exciting such coherences and hence do not suffer from phase errors in strongly coupled multiplets. Bipolar sequences also reduce contributions to diffusion-encoding from static background field gradients; these are not a problem under high resolution conditions, but in heterogeneous systems with strong internal field gradients caused by magnetic susceptibility differences they can complicate matters significantly. Adding balancing gradient pulses to the PFG-STE sequence gives the gradient compensated stimulated echo (GCSTE) sequence of Figure 3(c), which is a good general purpose sequence for systems lacking strong coupling; in the latter case the bipolar pulse pair stimulated echo (BPPSTE) sequence of Figure 3(d) is preferable.

With all pulse sequences for high resolution DOSY it is important to ensure that the desired coherence transfer pathway is followed. At first sight this might seem unimportant for a

sequence such as PFGSTE, since the gradient pulses might be expected to suppress the coherence transfer antiecho. However, even with strong gradient pulses the attenuation envelope for rejected signals only decays as the inverse of the pulse area. Small amounts of unwanted signal can therefore survive the pulse sequence, causing small intensity and phase anomalies and distorting the resultant diffusion spectrum. For the best results with PFGSTE-based sequences it is therefore important to use phase cycling. With BPPSTE, the issue is more critical, since without phase cycling any magnetization that does not experience perfect 180° pulses during the defocusing and refocusing periods will form a gradient echo over the relevant period and will not experience significant diffusional attenuation.

Where speed of measurement is important – and useful DOSY data can be obtained in as little as 30 s – a purge/homospoil pulse may be used in the diffusion delay to enforce zero coherence order in this period, and in bipolar sequences the positive and negative gradient pulses may be unbalanced in order to dephase magnetization not refocused by the 180° pulses. A final refinement is to add dummy pulses, where gradient amplifier duty cycle permits, before the start of a pulse sequence. These may be ramped down in amplitude as the diffusion-encoding pulses are ramped up, in order to keep the net energy dissipated the same for each transient; the pulses precondition the gradient amplifier and coil, and reduce gradient pulse area mismatch problems. A bipolar sequence which incorporates all three of these modifications and is suitable for “one-shot” (single transient per gradient value) use is shown in Figure 3(e).

The limitations imposed by non-uniformity of the pulsed field gradient are most effectively dealt with as described in Data Analysis, since this retains full sensitivity and resolution in the NMR data. A much simpler method of reducing the impact of gradient non-uniformity is to restrict the active volume of the sample to the most homogeneous region of the gradient (i.e., the region where the applied gradient is closest to linear). This may be achieved either by using selective excitation in the presence of a field gradient to select just a slice of the sample, or by physically restricting the length of the sample. In the former case care must be taken to avoid spurious echo phenomena, while in the latter case even the best susceptibility matching still results in a substantial degradation of the NMR lineshape.

A more serious limitation on DOSY measurements is the requirement that the motion of the spins in the sample be dominated by diffusion. Typical high resolution DOSY experiments use diffusion times Δ of a few tenths of a second, so for small molecules the mean square displacement over the timescale of the experiment is about $20 \mu\text{m}$. Coherent motion of the spins with a velocity of the order of $1 \mu\text{m s}^{-1}$ is thus sufficient to interfere with diffusion measurements even for small molecules; studies on macromolecules, and on nuclei with low magnetogyric ratio, can be vitiated by much slower motion (of the same order as continental drift). There is thus a severe potential problem of convection when attempting to use DOSY at temperatures above or below room temperature.

Where mobile solvents such as methanol or acetone are used, the onset of convection in a normal NMR tube with commercial probes is typically only a few degrees away from the quiescent sample temperature. The first sign of convection is usually the appearance of small phase errors

at higher gradient strengths; for low velocities, the phase error is proportional to the product of the gradient pulse width, diffusion time and gradient amplitude. Unfortunately, apparent phase errors are a common symptom of other instrumental problems, including lock disturbance, slow B_0 recovery, and gradient pulse area mismatch. The onset of convection can be delayed by using a capillary tube, particularly if the capillary is surrounded by a mobile (but NMR-silent) solvent, since the convection of the outer liquid helps reduce the temperature gradient along the capillary sample. A more general solution to the problem of coherent motion of the spins during DOSY experiments is to build velocity compensation into the pulse sequence. The sequence of Figure 3(f) uses a double stimulated echo¹⁴ to refocus the phase gradient caused by coherent motion. Such sequences, which can be extended by analogy with sequence 3(e) to avoid lock disturbance and hence give improved lineshapes, allow DOSY measurements to be performed over a much wider temperature range.

4.2 Heteronuclear 2D DOSY

The principal factor limiting the application of DOSY to the analysis of complex mixtures is the requirement that spectra be well-resolved if good diffusion resolution, and hence good discrimination between mixture components, is to be obtained. One way to improve resolution is to select for observation a nucleus such as carbon-13 that has a relatively high ratio of chemical shift dispersion to linewidth. Unfortunately there is a double price to pay on moving from protons to carbon-13, in the form of greatly reduced signal-to-noise ratio and a four-fold decrease in sensitivity to field gradients. The latter problem can be eliminated, and the former

somewhat reduced, if the carbon-13 signals measured are the result of polarization transfer from protons. Combining a proton pulsed field gradient stimulated echo sequence with INEPT (insensitive nuclei enhanced by polarization transfer) or DEPT (distortionless enhancement by polarization transfer) transfer to carbon-13 allows carbon signals to be measured which enjoy the usual signal enhancement and recycle time advantages of polarization transfer techniques, and show the same sensitivity to diffusion as proton signals. DOSY-DEPT and DOSY-INEPT¹⁵ can, where sensitivity permits, be very effective mixture analysis tools. One complication is the need to keep power deposition in the sample from decoupling to a minimum, since quite modest decoupling powers are sufficient to generate convection in mobile solvents.

4.3 3D DOSY

A more general approach to improving spectral resolution in DOSY is to extend experiments into a further spectral dimension. 3D DOSY experiments involve the measurement of a series of conventional two-dimensional spectra with increasing diffusion weighting, typically by prepending a pulsed field gradient stimulated echo sequence to the preparation period of a normal 2D experiment. Cross- and diagonal-peak volumes are then fitted to extract diffusion coefficients and standard errors and a 3D DOSY spectrum synthesized in a manner exactly analogous to 2D DOSY. DOSY-COSY,¹⁶ DOSY-NOESY¹⁷ and DOSY-TOCSY (total correlation spectroscopy)¹⁸ experiments have all been described, although most applications have been restricted to labeling 2D peaks with diffusion coefficients rather than carrying out the synthesis of a full 3D spectrum. The highest

Figure 4 400 MHz proton DOSY spectrum of a mixture of quinine (Q), geraniol (G) and camphene (C) in deuteriomethanol; signals are also seen for HDO (W) and TMS (T)

net resolution technique reported to date is DOSY-HMQC (heteronuclear multiple quantum coherence),¹⁹ which disperse signals according to proton shift, carbon-13 shift and diffusion coefficient.

5 EXAMPLES

Figure 4 shows a typical high resolution proton 2D DOSY spectrum for a simple mixture, illustrating some of the strengths and weaknesses of DOSY as a tool for the analysis of simple mixtures. The sample, a mixture of quinine, geraniol and camphene in deuteriomethanol, also contained TMS (tetramethylsilane) as reference, and residual water and monoproliomethanol. Spectral data were acquired at 400 MHz

using the GCSTE sequence of Figure 3(c); 10 spectra of 16 transients covering the range $0.6\text{--}10\text{ G cm}^{-1}$ in equal steps of gradient squared were measured with a diffusion time Δ of 0.5 s and gradient pulse widths δ of 2 ms, in a total time of 45 min. These parameters were chosen to give only modest (ca. 50%) attenuation for the signals of the slowly-diffusing quinine, in order to ensure that there was sufficient TMS signal for reference deconvolution at the higher gradient strengths. Spectra were processed with reference deconvolution based on the TMS line to give a Lorentzian lineshape of 1 Hz at half height, baseline corrected using cubic spline interpolation, and fitted with a modified exponential derived from gradient mapping experiments as described in Section 3.1.

Overall, the distribution of signals in the diffusion domain of spectrum of Figure 4 is dominated as expected by the

Figure 5 400 MHz ^1H - ^{13}C DOSY-HMQC data for the same mixture as Figure 4, with (left) the integral projection of the 3D spectrum onto the diffusion axis, and (right, from top) integral projections onto the ^1H - ^{13}C plane for the diffusion regions $5.9\text{--}6.9 \times 10^{-10}$ (quinine, Q), $9.0\text{--}10.0 \times 10^{-10}$ (geraniol, G), and $12.1\text{--}13.1 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ (camphene, C)

diffusion coefficients of the four main species present, quinine, geraniol, camphene and TMS. These appear as four strong distinct peaks in the integral projection of the spectrum onto the diffusion axis, shown at the left. Above 2 ppm, all of the signals appear at the expected positions in the diffusion domain, with one exception. At 4.9 ppm the quinine multiplet lies on top of the broader residual water signal, with the result that the apparent diffusion coefficients of the quinine signals are increased and that of the water slightly decreased. This effect can be reduced but not eliminated by the use of resolution enhancement to reduce the overlap between the signals; however, the shifts in the signals are simple, predictable and easily accounted for, and do little to damage the interpretability of the spectrum. Below 2 ppm the large number of aliphatic proton signals from the three main species gives rise to more severe overlap, with the result that a significant number of signals are displaced to lie at averaged apparent diffusion coefficients. As the diffusion projection shows, 95% of the overall signal intensity remains at the correct diffusion coefficient; in this sample only low intensity signals show significant deviations from their expected positions, although the difficulty of reproducing contour plots for spectra with such high chemical shift resolution exaggerates their apparent importance.

Where sensitivity considerations permit, 3D DOSY methods offer a large improvement in resolution. Figure 5 shows data from a 3D DOSY-HMQC (heteronuclear multiple quantum coherence) experiment¹⁹ on a similar sample of quinine, geraniol and camphene. Five diffusion-weighted HMQC datasets of 512×1024 complex data points were acquired in a total time of 17 h, with a diffusion time of 45 ms and pulse gradient strengths from 1 to 30 G cm^{-1} . Peak volumes were determined for all cross peaks and fitted to a simple exponential as a function of q^2 . The extra resolution afforded by separating signals according to both ^1H and ^{13}C chemical shifts now ensures that all signals, including those for the aliphatic protons, are well-resolved. Thus while the relative accuracy with which diffusion coefficients are determined is reduced compared to Figure 4 because of the small number of different gradient strengths used, the 3D experiment nevertheless successfully resolves all the signals in the mixture.

1 INTRODUCTION

In the CW NMR technique, as used in the early days of NMR (see Volume 1 of this Encyclopedia), the frequency spectrum was obtained directly as a function of the input rf or the strength of the magnetic field, B_0 . For the modern high resolution pulse NMR experiment a FID is recorded as a function of time, and the frequency spectrum is calculated as the FT (see *Fourier Transform Spectroscopy*) of this time domain signal. Despite the qualities of the FT, such as computational efficiency and numerical stability, in recent years improved spectral methods have been introduced into the analysis of NMR data. Among these methods the linear prediction method, described in this article, has been one of the most succesful.

There are two main reasons for the application of the linear prediction method to NMR data. One is to produce better spectra, i.e. to avoid the drawbacks that characterize the FT, particularly for multidimensional NMR data (see *Multidimensional Spectroscopy: Concepts*). The other reason for the use of the linear prediction method is to estimate spectral parameters (frequencies, signal intensities, signal widths, and phases) directly from the FIDs.

The drawbacks of the FT mentioned above are aliasing, (sin x)/ x modulation of the resonance signals, phase distortions, and pseudobaselines. Although we often refer to these effects as artifacts, they are caused by one of the advantages of the FT, i.e. the conservation of information. Thus, the fact that the time domain FID can be sampled only for a finite period of time and only as a limited number of discrete data points, must also be expressed in the frequency spectrum. Unfortunately, this information is kept in the form of the rather annoying effects mentioned above. These characteristics of the FT are quite general. In Section 2 of this article they are described in some detail for the special case of the NMR FID.

From the above it follows that in order to reduce the 'artifacts' in the spectrum we must apply an alternative spectral method that does not preserve all the information of the FID. In particular, we wish to suppress the information about the truncation, and preserve the information about the NMR resonance signals. As described in Section 3, this can be done by using the linear prediction method. Finally, in Section 4 it

is described how a detailed knowledge of the artifacts in the FT spectrum together with the principle of least squares can be applied to gain valuable information from NMR spectra.

2 THE FOURIER TRANSFORM OF THE FREE INDUCTION DECAY

On the assumption of multiexponential decay the sampled FID F_k can be expressed as

$$F_k = F(k\Delta t) = \sum_{j=1}^p I_j \exp[(i2\pi\nu_j - R_{2j}^*) \times (k \cdot \Delta t + T_{in}) + i\phi_j] \quad (1)$$

where k is an integer in the interval $[0, N - 1]$, Δt is the sampling interval, I_j is the amplitude of the j th exponential, and ν_j , R_{2j}^* , and ϕ_j are the frequency, the decay rate, and the phase, respectively. For severe overlap, strong coupling, or cross correlation it may not be possible to assign I_j to a specific nucleus, but this has no consequence for the following. Further, the symbol T_{in} is the initial time during which the signal has developed before the sampling is started, and i is the imaginary unit. Equation (1) represents the case of quadrature detection, where the signal is sampled as a series of complex numbers. To describe the real-valued case, which is not covered in this article, equation (1) should be added to its own complex conjugate.

Because of the discrete nature of F_k , the FT must be applied in its discrete form, i.e.

$$S_m = S\left(\frac{m}{n \cdot \Delta t}\right) = S\left(\frac{m}{T_{aq}}\right) = \sum_{k=0}^{N-1} F_k \exp(i2\pi km/n) \quad (2)$$

When F_k from equation (1) is introduced into equation (2), the expression can be evaluated as the finite sum of a geometrical progression. Thus, the analytical expression for the FT NMR spectrum is

$$S_m = S\left(\frac{m}{N \Delta t}\right) = S(\nu) = \sum_{j=1}^p A_j \frac{1 - \exp\{[i2\pi(\nu_j - \nu) - R_{2j}^*]T_{aq}\}}{1 - \exp\{[i2\pi(\nu_j - \nu) - R_{2j}^*]/F\}} \quad (3)$$

Here, ν_j is the independent frequency variable in the spectrum, $T_j = N \cdot \Delta t$ is the acquisition time, $F = (1/\Delta t)$ is the spectral width, and A_j is given by

$$A_j = I_j \exp[(i2\pi\nu_j - R_{2j}^*)T_{in} + i\phi_j] \quad (4)$$

Contrary to k , the number m is not necessarily an integer. This reflects the fact that the spectrum can be evaluated for any value of the frequency ν . However, when the fast FT procedure is applied to the N values of F_k , the spectrum is calculated only for integer values of m in the interval $[0, N - 1]$. If zeros are added at the end of the FID before the FT, the right-hand side of equation (3) still holds, because only

zeros are added to equation (2), but the variable m may now be a noninteger. If for example N zeros are added after the N points of the FID, the spectrum is calculated for $m = 0, \frac{1}{2}, 1, \frac{3}{2}, \dots, N - 1$.

Equation (3) consists of two periodic terms: one in the numerator with the period $1/T_{\text{aq}}$, and one in the denominator with the period $F = (1/\Delta t) = (N/T_{\text{aq}})$. Thus the entire expression has a period of F , i.e. the Nyquist frequency.¹ In order to avoid the implied aliasing of signals, a sufficiently short dwell time, Δt , must be chosen in order to assure that F is larger than all resonance frequencies in the spectrum. However, as shown in equation (3), the discrete spectrum still differs significantly from the theoretical spectrum, which is given as a sum of nonperiodic complex Lorentzians:

$$s(\nu) = \sum_{j=1}^p \exp(i\phi_j) I_j / R_{2j}^* \frac{1}{1 - i2\pi(\nu_j - \nu) / R_{2j}^*} \quad (5)$$

For the discrete spectrum to approximate the theoretical spectrum, F must be large compared with the involved decay rates R_{2j}^* , and to all relevant values of $\nu_j - \nu$. The latter condition corresponds to what is often referred to as ‘oversampling’, and is rarely fulfilled, particularly in multidimensional spectroscopy. Nonetheless, when these conditions hold, equation (3) is reduced to

$$S(\nu) = \left(F \sum_{j=1}^p \frac{A_j}{R_{2j}^*} \frac{1}{1 - i2\pi(\nu_j - \nu) / R_{2j}^*} + \sum_{j=1}^p A_j / 2 \right) \times \{1 - \exp\{[i2\pi(\nu_j - \nu) - R_{2j}^*]T_{\text{aq}}\}\} \quad (6)$$

as shown by Gesmar et al.² If the FID is allowed to decay completely during the sampling, i.e. $T_{\text{aq}} \gg (1/R_{2j}^*)$, the term in the second parentheses in equation (6) is very close to unity. This is the ideal discrete FT spectrum in that it is the best approximation to a sum of complex Lorentzians as expressed in equation (5). Even in this case, however, the FT spectrum differs from the theoretical spectrum. Firstly, because a frequency-independent term $\sum_{j=1}^p A_j / 2$ is present, and secondly, because each intensity I_j has been multiplied by the factor $\exp\{[i2\pi\nu_j - R_{2j}^*]T_{\text{in}}\}$, as can be seen from equation (4).

The first deviation results in a pseudobaseline in the FT spectrum. However, this pseudobaseline is removed in the ideal case when the first point of the FID is multiplied by $\frac{1}{2}$ before the Fourier transformation. This is particularly important for multidimensional spectroscopy, where the presence of baselines in the individual FIDs leads to ridges in the various dimensions.

The second deviation, namely the presence of the factor $\exp\{[i2\pi\nu_j - R_{2j}^*]T_{\text{in}}\}$, results in a frequency- and relaxation-dependent phase distortion of the FT spectrum. This phase distortion depends linearly upon the center frequencies ν_j of the individual signals, and not upon the independent spectral frequency variable ν . Therefore, the commonly used linear phase correction procedure, based on a linear relationship between the phase and the spectral frequency ν , is not always appropriate, although it suffices in most cases with modest phase distortions and narrow and well-separated signals. For extreme phase distortions, however, or for signals that are

broad and poorly separated, or when small signals are situated on the tail of a larger signal, the spectrum can be correctly phased only at the center of each signal, and undulations of the signal tails will occur. In order to reduce such effects, the value of T_{in} is normally kept as small as possible, despite the fact that the first few points of the FID are often of poor quality due to the electronic filtering and, eventually, overflow in the analog-to-digital converter. Thus, not even the ideal discrete Fourier transform spectrum is the ‘true’ spectrum as given by equation (5).

In many cases, and particularly in multidimensional spectroscopy, the FID is not sampled until the point where it has decayed completely, i.e. $T_{\text{aq}} \approx 1/R_{2j}^*$. In such cases, $1 - \exp\{[i2\pi(\nu_j - \nu) - R_{2j}^*]T_{\text{aq}}\}$ in equation (6) cannot be neglected, which results in an apparently misphased signal. Because the phase error depends on the position of the resonance frequency ν_j relative to the specific frequencies $\nu = (m/T_{\text{aq}})$ calculated by means of the FT procedure (see above), it appears to be random and cannot be corrected in the general case. Note that for signals with $\nu_j = (m/T_{\text{aq}})$ (m is an integer), misphasing due to the truncation will not occur. Furthermore, because the pseudobaseline level $\sum_{j=1}^p A_j / 2$ is also altered by $1 - \exp\{[i2\pi(\nu_j - \nu) - R_{2j}^*]T_{\text{aq}}\}$, the above-mentioned multiplication of the first data point by a factor of $\frac{1}{2}$ will not work, and the area between the signal curve and the baseline is no longer a measure of the relative signal intensity. The amount of intensity that has leaked into the pseudobaseline depends on ν_j and R_{2j}^* for individual resonances. As can be seen from equation (6), the pseudobaseline problems are reduced considerably when the spectral width F is significantly larger than the frequency range covered by the resonances, i.e. when the FID is oversampled (see above).

When m is an integer, $1 - \exp\{[i2\pi(\nu_j - \nu) - R_{2j}^*]T_{\text{aq}}\} = 1 - \exp\{[i2\pi\nu_j - R_{2j}^*]T_{\text{aq}}\}$ and no oscillations are observed in the spectrum. However, as already mentioned, by zero filling the FID, the frequencies $\nu = (m/T_{\text{aq}})$ in the FT spectrum can be calculated for fractional values of m also, in order to increase spectral resolution. In this case the periodicity of the factor $1 - \exp\{[i2\pi(\nu_j - \nu) - R_{2j}^*]T_{\text{aq}}\}$ is seen in the spectrum as signal side lobes (‘wriggles’) with a period of T_{aq}^{-1} in connection with the resonances whose components in the free induction decay have been truncated.

In the following sections it is described how the deviations between the theoretical spectrum [equation (5)] and the discrete FT spectrum can be reduced or even eliminated.

3 THE LINEAR PREDICTION METHOD

Since linear prediction was introduced into the field of NMR spectroscopy by Barkhuijsen et al., it has been used as an effective tool in the analysis of time domain NMR data.^{3,4} It is applied in a number of ways, both qualitatively and quantitatively. Qualitatively it is used as a preprocessor to the FT in order to improve the resulting spectra. Quantitatively it can be used as an estimator of the spectral parameters, i.e. the frequencies, linewidths, intensities, and phases. In all cases, it eliminates or reduces considerably the deficiencies of the FT such as aliasing, truncation errors, phase distortions, and ridges in one- and multi-dimensional NMR spectra. In this section the principles of the linear prediction method are reviewed briefly. In Section 3.1 the qualitative application of

the method is illustrated, and the quantitative application of the linear prediction method is demonstrated in Section 3.2.

The FID signal F_k , given as a sum of p exponentially damped sinusoids sampled at regular time intervals [equation (1)], has the following property:

$$F_k = \sum_{m=1}^p f_m F_{k-m} \quad (7)$$

disregarding the effect of the noise.⁵ Here f_m is the m th forward prediction coefficient. Since f_m is independent of k it can be determined from the experimental data points, and subsequently used to extrapolate the FIDs. An interesting alternative to direct extrapolation of the FID, the linear prediction z -transformation (LPZ) method, has been suggested by Tang and Norris.⁶

The prediction coefficients are related to the frequencies ν_j and the decay rates R_{2j}^* , through the characteristic polynomial:

$$z^p - \sum_{m=1}^p f_m z^{p-m} = P(z) \quad (8)$$

since the roots C_j of this polynomial are given by⁵

$$C_j = \exp[(i2\pi\nu_j - R_{2j}^*)\Delta t] \quad (9)$$

For an experimental FID, the precise number of signals contained in the FID is, in general, unknown a priori. Therefore, the applied number of prediction coefficients must be sufficiently large ($>p$) to ensure the determination of all the involved complex exponentials. This results in an excess of roots of the characteristic polynomial in equation (8). However, as shown by Kumaresan,⁷ the roots are divided into two classes: one that contains the p signal roots conforming to equation (9), and another that contains the extraneous roots. Furthermore, in the case of backward prediction, i.e.

$$F_k = \sum_{m=1}^p b_m F_{k+m} \quad (10)$$

the two classes can be separated, since the extraneous roots still fall inside the unit circle, whereas the signal roots C_j are situated outside the unit circle. In the case of forward prediction [equation (7)], both classes fall inside the unit circle. This is, in principle, of no consequence if the coefficients are used for an extrapolation of the FID, since this requires both classes of coefficient. In practice, however, the presence of noise may occasionally result in roots that fall outside the unit circle, corresponding to noise components with negative decay rates (see below).

3.1 Qualitative Application

Qualitatively, linear prediction is used as a preprocessor to the FT in order to improve the resulting spectra.⁴ An example of this application is the reconstruction of the first few data points of an experimental FID where these points have been

corrupted by pulse breakthrough or by electronic filtering.⁸ The presence of such corrupted data points may result in a severe baseline distortion, as illustrated in Figures 1(a) and (b). Although a deletion of the points would, in principle, remedy this problem, such a deletion would create a new problem, namely a dramatic first-order phase distortion of the FT spectrum. However, as shown in Figures 1(c) and (d), a reconstruction of the first six data points from the succeeding ones using equation (10) results in a straight baseline of the FT spectrum. Obviously, backward linear prediction extrapolation of the FID also provides a method of correcting dramatic first-order phase distortions, as occurs in cases where the experimental conditions introduce significant initial delays, e.g. semiselective soft pulses.

For truncated FIDs, forward extrapolation can be applied in order to reduce the truncation errors, and thus increase the resolution.⁹ This is particularly the case in three- or higher-dimensional spectra.^{10,11} Because of a limited accumulation time, the time domain data for the slowest incrementing time dimension are normally truncated, which results in a limited resolution. Also, for natural abundance two-dimensional heteronuclear correlation spectra, forward extrapolation has proved useful. Because of the low sensitivity that characterizes these spectra, the data acquisition in the t_1 domain should be confined to only the first and most intense part of the FID. This, however, is meaningful only if the associated truncation errors can be alleviated by forward linear prediction of the FID.

In both cases of forward extrapolation the reliability of the extrapolation depends on the number and the quality of the experimental data used for the extrapolation. This can be realized by considering a noiseless FID containing N sinusoids. Here only $4N$ data points would be necessary to determine the $4N$ parameters that are involved (i.e. the frequencies, the linewidths, the intensities, and the phases of the N signals) and, thereby, to reproduce the entire FID. When noise is present, as in experimental data, the number of data points and linear prediction coefficients used for the extrapolation must be increased considerably. Normally, the number of data points should exceed the number of linear prediction coefficients by at least a factor of 3.

As mentioned above, the noise may also give rise to roots outside the unit circle. Since these roots correspond to noise components with negative decay rates, an extrapolation that includes the corresponding linear prediction coefficients would result in an extrapolated FID which increases with increasing time. Preferably, this problem should be solved by including more experimental information in order to obtain a more stable solution, and thus remove the extracircular roots and ensure the decay of the extrapolated FID. If this is not possible, the roots may simply be reflected to fall inside the unit circle.⁸ In any case, it is mandatory to apply equation (10) in order to check for roots outside the unit circle and, if necessary, to construct a modified set of roots from which a new set of linear prediction coefficients can be calculated. Omission of this procedure may result in artifactual peaks in the resulting spectra.

The effect of forward extrapolation is illustrated in Figure 2 which shows an experimental FID along the t_1 dimension in the methyl region of the C-H correlation spectrum of insulin, together with the FT. The original time domain data were Fourier transformed in t_2 , so that the FID in Figure 2 is a

Figure 1 The first slice along the F_2 dimension in a two-dimensional HOHAHA spectrum of dimeric insulin. (a) The FT spectrum. (b) The first 50 data points of the FID. Note that the fourth data point in the FID is severely damaged, which gives rise to the undulating baseline in (a). (c) The first six data points of the FID were deleted and recalculated from 18 linear prediction coefficients using equation (10). The linear prediction coefficients were determined from 36 equations of the type of equation (10), k ranging from 7 to 42. Note that the vertical scale is changed. sum of several proton signals modulated by the frequencies of the attached ^{13}C nuclei. Here Fourier transformation of the original 512 experimental data points alone would result in an unacceptably low digital resolution, while zero filling would give rise to truncation errors in the form of a sinc function ('wiggles') superimposed on the signals. Although this artifact can be removed by digital filtering [Figures 2(a) and (c)], it can be done only by sacrifice of resolution. Only if the FID is extrapolated by linear prediction to an almost complete decay [Figure 2(b)] is the information, inherent in the experimental FID, retained [see Figure 2(d)].

It should be emphasized that, whereas the backward reconstruction of the first few corrupted data points of the FID is normally a 'safe' modification, the forward extrapolation of a FID should be applied with care. This holds because the number of reconstructed data points in the backward reconstruction is small compared with the number of linear prediction coefficients that can be calculated, and because the fine structure of the spectrum is not influenced by the initial points in the FID. Similar favorable conditions do not apply in the case of forward prediction, since here a more extensive extrapolation is often desirable in order to ensure a complete decay. In general, the number of complex linear prediction coefficients must be at least equal to the number of resonances in the FID, and preferably exceed it by several factors, the surplus necessary depending on the signal-to-noise ratio. Should this condition not be fulfilled, the accuracy by which the frequencies are reproduced by the extrapolation may be too low, making the extrapolation less valuable, or even meaningless, if carried too far. In such cases a shorter extrapolation in combination with a window function may be appropriate.¹⁰

3.2 Quantitative Applications

3.2.1 One-Dimensional Data

The aim of the quantitative linear prediction approach is to obtain the spectral information from the FID directly as the parameters I_j , ν_j , R_{2j}^* , and ϕ_j , i.e. to estimate the involved intensities, frequencies, decay rates, and phases. In addition, the corresponding standard deviations should be evaluated. The quantitative linear prediction method is based on the classical work by Baron de Prony, further developed by Kumaresan and Tufts, and introduced into the field of NMR spectroscopy by Barkhuijsen et al. as the linear prediction singular value decomposition method (LPSVD).^{3,12,13} The basic principle of the method is described below.

In order to find n linear prediction coefficients from N data points, equation (10) is set up for $N - n$ values of the index k , where n should be chosen to be considerably larger than the expected number of resonances. The linear prediction coefficients are found by singular value decomposition of equation (10), and subsequently the roots of the characteristic polynomial in equation (8) are found. As explained in the previous section, the extraneous roots, caused by the excess of linear prediction coefficients, can be separated from the signal roots C_j because the former fall inside the unit circle, while the latter fall outside because of the decay of the complex

exponentials. For backward prediction $C_j = \exp [(-i2\pi\nu_j + R_{2j}^*) \Delta t]$ and F_k can be expressed as

$$F_k = F(k \Delta t) = \sum_{j=1}^p I_j \exp(i\phi) C_j^{-(k+T_{in}/\Delta t)} \quad (11)$$

where F_k is seen to depend linearly on $I_j \exp(i\phi)$. For N data points, equation (11) can be expressed for N values of k , and because $C_j^{-(k+T_{in}/\Delta t)}$ is known, the complex values of $I_j \exp(i\phi)$ can be determined by a linear least-squares calculation. From the complex values of C_j and $I_j \exp(i\phi)$, the spectral parameters ν_j , R_{2j}^* , I_j , and ϕ_j are easily determined. Thus, the spectral parameters needed to describe the resonances in the FID can be determined without any a priori assumptions about their values. As only the parameters I_j and ϕ_j are included in the final least-squares calculation, true least-squares estimates of the standard deviations cannot be evaluated from the corresponding normal equation matrix. However, as established by Barkhuijsen et al.¹⁴ in a later paper, the Cram r Rao lower bounds can be used as reasonable substitutes.

Although the spectral parameters contain all the relevant information about the FID, a noiseless FID is often simulated and subsequently Fourier transformed to make a direct

comparison with the FT spectrum possible. An example from the original paper by Barkhuijsen et al.³ is shown in Figure 3.

The fact that no initial assumption about the spectral parameters is needed increases the value of the linear prediction method for complicated spectra with many narrowly spaced and overlapping resonances. In order to ensure sufficient resolution in such cases a very large number of linear prediction coefficients is needed in equation (10). This often results in computations that are unfeasible with the classical procedures for solving linear equations such as singular value decomposition, QR, and Cholesky decomposition, all of which have been applied to the linear prediction method in order to solve equation (10).^{15,16} Therefore, dedicated fast algorithms have been developed for both the singular value decomposition method and the QR method.^{17,18} Consequently, for one-dimensional linear prediction calculations the computational bottleneck is no longer associated with solving equation (10), but rather with the rooting of the characteristic polynomial. As shown in Figure 4, it is possible, at present, to apply more than 10 000 linear prediction coefficients to ensure sufficient resolution.

3.2.2 Two-Dimensional Data

The complete quantitative linear prediction analysis of two-dimensional NMR data was developed by Gesmar and Led, as

Figure 3 (a) In vivo ^{31}P NMR spectrum, computed by cosine fast Fourier transformation of 768 data points, using the optimal signal-to-noise ratio filter with a time constant of 0.015 s, and putting the three initial data points equal to zero. reviewed briefly here.¹⁹ A two-dimensional FID, $F_{l,k} = F(l \Delta t', k \Delta t)$, sampled at regularly spaced time intervals Δt and $\Delta t'$ in the two dimensions, conforms with equation (1) only if $I_j \exp(i\phi_j)$ is substituted by

$$D_{l,j} = \sum_{h=1}^{p_j} I_{h,j} \exp(i\phi_{h,j}) \exp[(i2\pi\nu'_h - R_{2h}^*)l \Delta t'] \quad (12)$$

where the label prime indicates the second dimension. The parameter $I_{h,j}$ is the intensity of the two-dimensional signal and p_j is the number of correlations of the j th resonance. Equation (10) is still valid for any value of l , and because $\exp[(i2\pi\nu_j - R_{2j}^*) \Delta t]$ does not depend on l , neither do the backward coefficients b_m . Thus, an equation similar to equation (10)

$$F_{l,k} = \sum_{m=1}^p b_m F_{l,k+m} \quad (13)$$

applies in the two-dimensional case for any value of k and l , i.e. the p linear prediction coefficients apply in the t dimension for all values of l . Therefore, equation (13) can be set up and solved for all values of l simultaneously. After the determination of the b_m values, the corresponding characteristic polynomial equation is solved, and the frequencies ν_j and the decay rates R_{2j}^* are found from the C_j values for the t dimension exactly as in the one-dimensional case. Since the C_j values are known at this point, the values of the $D_{l,j}$ terms that have replaced the I_j terms can be found for each value of l in the same way as the I_j values were found for the one-dimensional case. Thus, for each resonance ν_j a series of values of $D_{l,j}$ as a function of l can be evaluated. Now, because $D_{l,j}$ itself is a sum of complex exponentials, as can be seen from equation (12), the linear prediction principle applies once again. Therefore,

$$D_{l,j} = \sum_{m=1}^{p_j} b'_{j,m} D_{l+m,j} \quad (14)$$

where $b'_{j,m}$ represents the t' backward coefficients that belong to the j th resonance. For each resonance ν_j a complete one-dimensional linear prediction calculation, which also includes the rooting of the characteristic polynomial and subsequent linear least-squares determination of the intensities and phases, is carried out. Thus, in addition to ν_j and R_{2j}^* , estimates of $\nu_{h'}$ and R'_{2h^*} are produced together with the value of $I_{h,j}$ and $\phi_{h,j}$, i.e. a complete determination of the spectral parameters of the two-dimensional FID has been achieved.

The applicability of the two-dimensional quantitative linear prediction procedure was demonstrated in the original paper by the determination of the spectral parameters from the ^1H phase modulated COSY FID of threonine in D_2O .¹⁹ The parameters are listed in the original paper, and the quality of the estimation is illustrated in Figure 5 by a two-dimensional Lorentzian-shaped reconstruction of a (β -CH, CH_3) cross peak.

4 LEAST-SQUARES FOURIER TRANSFORM TECHNIQUES

In this section it is described how the spectral parameters I_j , ν_j , R_{2j}^* , and ϕ_j can be estimated from the FT spectrum, unbiased by the deviations from the theoretical spectrum described in Section 2.²⁰ As mentioned previously, no information is lost by the Fourier transformation and, therefore, the spectral parameters can be evaluated from the FT spectrum as well as from the FID. Furthermore, the noise in the FT spectrum is uncorrelated with the zero mean and constant

Figure 5 (a) Expansion of the (β -CH,CH₃) multiplet in the sine bell filtered two-dimensional absolute mode Fourier transform spectrum. (b) Spectrum of the same region, calculated from the parameters estimated by the two-dimensional linear prediction procedure. The signals are pairwise in counterphase, but the phases have been set to zero in the displayed spectrum. (Reproduced by permission of Academic Press, Inc. from H. Gesmar and J. J. Led, *J. Magn. Reson.*, 1989, **83**, 53)

variance if the same holds for the FID, a condition that is generally assumed to be true.² Thus the spectral parameters I_j , ν_j , R_{2j}^* , and ϕ_j can be estimated by a nonlinear least-squares fit of equation (3) to the FT spectrum. It should be emphasized, however, that unbiased estimates of the spectral parameters are obtained only by application of this exact expression for the discrete FT of a multiexponential decaying FID. Any attempt to fit Lorentzian signals to the FT spectrum will lead to biased values of the spectral parameters, as discussed in Section 2. In order to ensure that the spectral noise is uncorrelated, it is also important that the FID is neither zero filled nor manipulated in any other way.

An example that demonstrates the result of a least-squares fit of equation (3) to an FT spectrum is shown in Figure 6. Here the ¹H FT NMR spectrum of *N*-methylacetamide in water is presented together with a simulated spectrum, recalculated from the parameters estimated in the least-squares fit. The small signals are ¹³C satellites from the abundant *trans* isomer and the methyl resonances from the *cis* isomer. Because of the 6000 : 1 intensity ratio between the large water signal and the smallest signals of the solute, the latter are severely affected by aliasing. However, because equation (3) is used in the least-squares analysis, unbiased spectral parameters

Figure 6 (a) The ¹H NMR absorption mode FT spectrum of a 2.5 M solution of *N*-methylacetamide in water at pH 5.2. In the upper spectrum the vertical scale is increased by a factor of 100. (b) Simulated spectrum based on the parameters derived from the experimental spectrum corresponding to (a). The same linear phase correction was used in both spectra. (Reproduced by permission of Academic Press, Inc. from F. Abildgaard, H. Gesmar, and J. J. Led, *J. Magn. Reson.*, 1988, **79**, 78)

are obtained for all signals, even the small ones. Thus, the intensity ratio between the methyl signals of the *trans* isomer and their ¹³C satellites was estimated as $1.11\% \pm 0.10\%$, which is in agreement with the expected concentration ratio of 1.12%. Likewise, the concentration of the *cis* isomer at 300 K was estimated to $1.60\% \pm 0.10\%$ of the total amount of *N*-methylacetamide. This also compares favorably with the previously estimated value of 3%. A table, that contains all the estimated spectral parameters and their standard deviations can be found in the original paper.²⁰

Because the spectrum $S(\nu)$ represented by equation (3) depends on the resonance frequency ν_j and the decay rate R_{2j}^* in a nonlinear fashion, the least-squares analysis must be performed iteratively and requires an estimate of reasonable initial values of these nonlinear parameters. This represents a difficult and time-consuming task and may even be impossible for complicated spectra. One way to solve this problem is to perform a linear prediction analysis of the corresponding FID and use the linear prediction estimate of the frequencies and

decay rates as initial values for the least-squares iterations. Alternatively, one can proceed as proposed by Kumaresan et al.,²¹ who have designed a sequence of iterations that requires only very crude initial values. The advantage of this approach is that no polynomial rooting is needed, as in the linear prediction procedure. However, unlike the linear prediction procedure, no 'fast' algorithm exists for the solution of the involved equations, and thus the choice of procedure must depend on the complexity of the NMR spectrum, and on the available computational possibilities. Still, unbiased estimates of the spectral parameters I_j , ν_j , R_{2j}^* , and ϕ_j can be obtained with both methods, because both include a least-squares calculation based on equation (3).

5 CONCLUSION

The spectral methods described in this article (extrapolation of the FID by linear prediction, quantitative linear prediction, and least-squares FT) have all proved to be very useful in NMR spectroscopy. The major drawbacks of these methods have been the extensive computing time required and the need for very large amounts of computer memory. However, the new 'fast' algorithms together with the substantial improvements in minicomputers have reduced these drawbacks considerably, and made the use of linear prediction and least-squares analyses feasible on standard computational equipment that is normally available in NMR laboratories today.

1 INTRODUCTION

Fourier transform (FT) spectroscopy employs wideband excitation to simulate simultaneously all the transition lines of a nuclear magnetic resonance (NMR) spectrum to produce a time-dependent response signal. An FT is applied to the response signal and produces an NMR spectrum. The FT is a mathematical process for converting a signal that is a function of time to one that is a function of frequency.

The wideband excitation may be produced by several different methods, the most common in use today being pulsing of the applied radiofrequency (rf) field. Another method is modulating an rf by a random or pseudorandom noise source. Wideband sources with almost any spectral distribution may be generated using modern pulse programmers and frequency synthesizers controlled by digital logic. A method related to FT spectroscopy uses a very rapid scan of the rf source through the NMR spectral region.

In the pulsed NMR method, the time-dependent NMR response, called the free induction decay (FID), is sampled at uniform time intervals after the termination of the rf pulse. Each time sample is digitized and stored in a digital memory. To improve the sensitivity, the experiment may be repeated, the responses of subsequent pulses sampled at the same uniform time intervals, and the digitized values of each sample added to the value previously stored for the corresponding time interval. When a sufficient number of samples have been stored, the FT is applied, yielding an output spectrum that is a function of frequency. The advantage of FT NMR spectroscopy is the gain in sensitivity that can be obtained. For ^1H or ^{13}C NMR in liquid samples the gain can exceed a factor of 100.

2 HISTORICAL BACKGROUND

The FT is named after the French mathematician Jean Baptiste Joseph Fourier (1768–1830). Fourier taught at the École Normale in Paris when it opened in 1795, and later at the École Polytechnique. In 1801 he became Prefect of Isère, based at Grenoble. Here he investigated heat conduction, and in 1807 announced his use of a series of sines and cosines

of integral multiples of a variable to represent almost any function. This idea originated in the works of Leonhard Euler (1707–83) and Daniel Bernoulli (1700–82). In 1816, Fourier moved to Paris, and in 1817 was made a Member of the French Academy of Science. In 1822 he published *Théorie Analytique de la Chaleur* in which he fully developed the theory and mathematics of the series now known by his name.

Spectroscopy started with optical spectroscopy, the dispersing of light into its spectral components or colors. In 1607, Isaac Newton illustrated that a beam of light, after passing through a glass prism, forms an elongated multicolored image called a spectrum. In 1802, Thomas Young developed the wave theory of light and related color to wavelength. In 1859, G. R. Kirchhoff set out the general law connecting absorption and emission of light and showed that each species of atom has a uniquely characteristic spectrum. In 1881, A. A. Michelson invented the interferometer and used it to measure accurately the wavelengths of a number of atomic emission lines relative to the standard meter. In his monograph of 1907, Michelson explained the connection between the spectral pattern of a light beam and the corresponding time domain signals, i.e. that one can be derived from the other through an FT.¹ The Michelson optical interferometer made possible multiplex spectrometry, i.e. recording of all the spectral intervals simultaneously. The full power of this technique for increasing the sensitivity of infrared spectrometry was pointed out by Fellgett in 1951² and is known as the ‘Fellgett advantage’ or ‘multiplex advantage’. The technique is unsuitable for NMR, however, because of the much longer wavelengths of NMR spectral frequencies.

NMR spectroscopy began with the discovery of the technique by Purcell and co-workers at Harvard³ and Bloch and coworkers at Stanford,⁴ reported early in 1946. The method used to obtain a spectrum was either to scan slowly the driving rf or the polarizing magnetic field strength. The resulting resonance could be displayed on an oscilloscope or on a strip chart recorder. This slow passage or continuous wave (CW) method was used for the first 20 years of NMR spectroscopy.

Some of the concepts of pulsed NMR were contained in the introductory section of Bloch’s first detailed paper about NMR.⁵

Not only a weak rf field, acting at resonance over very many Larmor periods, can produce an appreciable nuclear change of orientation, but also a strong field pulse, acting over only a few periods. Once the nuclear moments have been turned into an angle with the constant field, they will continue to precess around it and likewise cause a nuclear induction to occur at an instant when the driving pulse has already disappeared. It seems perfectly feasible to receive thus an induced nuclear signal of radiofrequency well above the thermal noise of a narrow band receiver.

The transient signal described here became known as the FID. Bloch did not specifically treat this case in the remainder of his paper. The concept appears to be covered by some of the broad claims of the Bloch–Hansen patent;⁶ however, no specific application is shown that makes use of this technique.

Transient effects, commonly called ‘wiggles’, were observed in many of the early experiments. They occur when one sweeps so rapidly through resonance that either thermal equilibrium is not achieved or the adiabatic condition is not satisfied. The wiggles were treated theoretically by Jacobsohn and Wangsness.⁷ For the conditions mentioned above, the nuclear

moment fails to precess in step with the applied rf, and a beat due to the interference of these two separate frequencies is seen. Later, Torrey⁸ analyzed a similar transient case that occurs when one establishes a nonequilibrium situation and then fixes the experimental parameters, including the strength and frequency of the rf field and the value of the polarizing field. Thus some transient effects were observed quite early, but they were not observed in the absence of an rf field as described by Bloch for the FID.

In October 1948, Russell Varian filed a patent application entitled 'Method and Means for Correlating Nuclear Properties of Atoms and Magnetic Fields'.⁹ The patent describes a specific method for changing the orientation of the nuclear moments so that they form an angle with the magnetic field, usually the Earth's field. A polarizing field is established at an angle with respect to the field to be measured (which is usually the Earth's magnetic field). After a nuclear polarization is established, the polarizing field is quickly shut off, leaving the nuclear moments at an angle with the Earth's field. They then precess about the direction of the Earth's field and, in so doing, induce a voltage in a coil surrounding the sample. This coil is coupled to a sensitive amplifier, the output of which is connected to a means of measuring the precessional frequency, which is proportional to the Earth's magnetic field strength. In the original systems, a frequency counter was used to determine the frequency. A reed frequency meter, which is a crude Fourier analyzer, was used in a later portable magnetometer.

In the year 1949–50, Hahn performed a number of experiments that made use of the pulsed rf field methods suggested by Bloch. He used a combination of an inversion pulse and a rapid scan through the resonance region to measure the thermal relaxation time of water.^{10a} Later he described the FID signals that follow a short pulse and developed the theory and experimental techniques of spin echo NMR. With the spin echo technique he measured the NMR relaxation times T_1 and T_2 .^{10b,c} Hahn and Maxwell analyzed the complex

echo patterns found in molecules that contained spin-coupled chemical groups.¹¹

In August 1956, Russell Varian filed a patent¹² which contained the major concepts of FT NMR as a method of increasing the sensitivity of NMR spectrometers. Here a wideband frequency source is used to excite simultaneously all the resonance lines in an NMR spectrum. After storing the responses, an FT analyzer is used to convert the response into a frequency spectrum. The system described in his patent is illustrated in Figure 1. It is stated in the patent that 'the wide band frequency source may comprise, for example, a pulse generator wherein the pulses are regulated to give Fourier components over the desired frequency range or a white noise source having the required bandwidth'. In this system he also provided a field/frequency control using a NMR reference sample. Signals from the analytical and reference samples are mixed together to obtain a signal at the difference frequency, thereby eliminating the effects of frequency or field drift. Two different Fourier analyzer systems are described: in one the signal is recorded on photographic film, and in the other it is recorded on magnetic tape. In the first system, the FT is performed by using the film as a diffraction grating in an optical spectrometer arrangement. The spectrum, i.e. the FT, is recorded on a second film by a beam of light that is diffracted by the image on the first film. After it has been developed, the second film is read with a photoelectric densitometer and recorded on a strip chart recorder. In the magnetic tape system the Fourier analysis is performed by playing the recorded signal to a mixer and sending the output through a low-pass filter and detector to the strip chart recorder. The mixer receives a reference signal from a variable-frequency oscillator. The frequency of this oscillator determines the frequency component of the output spectrum.

Because of their complexity, neither of these systems was built. However, the claims of the patent were sufficiently broad to cover practical systems that were developed later. From a reading of the patent it is obvious that Russell Varian had a clear understanding that the NMR response to a wideband

Figure 1 The FT NMR system described in the Russell Varian US Patent¹²

source and the spectrum formed an FT pair. Before the patent issued in 1966, Lowe and Norberg¹³ had also pointed out that the FID and spectrum formed an FT pair.

In the early 1960s, the need for greater sensitivity was growing. The increase in strength of the polarizing magnetic field was a help, as was the repetitive averaging of spectra by adding together many spectra in a computer of average transients (CAT) that became available about this time. The multiplex advantage, as suggested by the Varian patent, seemed to offer increased sensitivity without taking additional time to perform time averaging. In 1962, Anderson proposed a multichannel NMR spectrometer to make use of the multiplex advantage. He proposed using a chopper wheel to generate a band of frequencies which, after mixing with an offset frequency, could be applied to produce simultaneous resonance of the sample nuclei. The responses, after mixing with the same offset frequency, could be demodulated by the same chopper wheel and provide simultaneous multiple output signals in real time¹⁴ (see also *Anderson, Weston A.: Early NMR Experiences and Experiments*). These output signals could be integrated to achieve the desired signal-to-noise ratio. Before the chopper wheel was put into operation, Anderson realized that a series of pulses would be a better way to achieve a band of discrete rf fields. After mixing, the response signals could be stored using a CAT and then Fourier transformed by a computer. This approach was even closer to the Varian patent. The necessary equipment was assembled and the idea successfully tested by Richard Ernst. In the early experiments Ernst and Anderson found a sensitivity enhancement of more than 10 in experiments using the same data acquisition time (Figure 2) (see *Anderson, Weston A.: Early NMR Experiences and Experiments*).¹⁵

The improvement in sensitivity provided by the FT technique, compared with the previous field or frequency scanned experiments, is determined primarily by the ratio of the spectrum width F and the linewidth of a single transition $\Delta = 1/\pi T_2$. The time taken to obtain a spectrum by an FT experiment yielding essentially the same signal-to-noise ratio is reduced by a factor of F/Δ . By signal averaging, the signal-to-noise ratio increase is proportional to the square root of the number of averaged spectra. Thus, to first order, the FT technique provides an increase in the signal-to-noise ratio by a factor of approximately $\sqrt{(F/\Delta)}$ for the same total data collection time. With the larger spectral widths arising from

the greater magnetic field strengths of modern systems, the gain in the signal-to-noise ratio can be a factor of 100 or more for ^{13}C or ^1H experiments in liquid samples.

The use of a broadband noise source was demonstrated independently by Ernst¹⁶ and Kaiser.¹⁷ In these experiments a pseudorandom sequence was used to modulate the rf phase of the excitation to produce a wideband noise source. The advantage of the pseudorandom sequence is its predictable spectral properties and constant rf power. The rf power level is far lower than that required for pulsed FT; however, the simultaneous radiation and detection can lead to line broadening that is absent in pulsed FT spectroscopy.

In the rapid scan approach,¹⁸ the rf field is quickly scanned through the NMR spectral region causing wiggles, as described above. The spectrum is corrected by a convolution with a scan of a single line made under identical conditions, or by one that is simulated on a computer. The signal from a single line resembles its FID, except that the frequency of the wiggles increases as the rf frequency is swept away from the resonance condition.

With flexible pulse programmers and frequency synthesizers that can be digitally controlled, an excitation function can be generated with virtually any spectral distribution by controlling the width, amplitude, phase, and perhaps frequency, of each pulse or pulse segment. This concept was originally applied to spin decoupling by Tomlinson and Hill,¹⁹ and later used to produce composite pulses for the suppression of solvent lines and for other applications.²⁰

In 1971, J. Jeener proposed that the Fourier transformation technique be extended into a second dimension, from which information could be extracted using additional pulses.²¹ In 1974, Ernst and his group demonstrated the technique and showed how it could be particularly useful in analyzing large molecules.²² A first pulse or group of pulses was used to establish a coherent nonequilibrium state in the spin system. The state of the spin system then evolves during a period called the 'evolution period'. A second pulse or pulse group then causes mixing of the evolved states. The detection period follows the mixing period. An FT is applied to the signals recorded during the detection period. Repeating the experiment for different evolution times yields a two-dimensional array of data. A second FT is applied with respect to this second time dimension, the evolution time, to produce a two-dimensional frequency spectrum.

Variations of the two-dimensional experiment can yield a wealth of information. Some of the more important applications involve tracing out the molecular structures by resolving spin couplings between protons, protons and ^{13}C , and between ^{13}C atoms. Overhauser types of experiment yield information on the conformation of polypeptides and small proteins. Overlapping lines are often resolved by spreading the spectrum out in a second or a third dimension.^{23,24}

Magnetic resonance imaging (MRI) is a field in which FT techniques are essential. MRI began when Paul Lauterbur proposed the use of NMR for imaging in a manner analogous to the use of computerized tomography (CT) in X-ray imaging. Lauterbur's critical idea was to use magnetic field gradients, making the frequencies of the NMR resonance signals dependent upon the spatial position of the resonant nuclei.²⁵ A number of techniques developed by Hinshaw made use of the multiplex advantage of FT NMR. Generally, the techniques involved simultaneously detecting all the resonances in a

Figure 2 The FT NMR system described by Anderson and Ernst¹⁵

line or plane with the spatial positions coded by magnetic field gradients, and later reconstructing by the back-projection used in CT.²⁶ In 1975, Ernst proposed a way of acquiring and reconstructing MRI data that was similar to the two-dimensional spectroscopic method.²⁷ A magnetic field gradient is applied during the evolution period between pulses, and an orthogonal gradient is applied during the detection period. By repeating the experiment a number of times, each time incrementing the duration of the evolution time, a series of responses is collected. Applying a double FT with respect to the different times yields a cross-sectional image. The method was readily extended to three dimensions. This Fourier imaging technique, and a modified form known as spin warp imaging,²⁸ is the most frequently used method of MRI.

Resonances from nuclei in solid samples are split and shifted by the static dipole–dipole coupling between nuclei and by quadrupole coupling of nuclei that have electric quadrupole moments. Because the splittings and shifts depend upon the orientation of the interaction with respect to the polarizing field, resonances in a polycrystalline sample are further broadened. As a result, the FID from nuclei in a solid can be very short, and instrumental limitations of finite rf pulse lengths and receiver recovery times limit its direct observation.

Spin echo techniques¹⁰ can be used to overcome partially the problem of short FID transients that decay during the receiver dead time following the excitation pulse. The techniques are suitable for a polycrystalline material with strong dipole or quadrupole couplings. The basic spin echo technique uses two excitation pulses separated by a short time interval. The magnetization then rephases to form a dipolar echo²⁹ or quadrupolar echo.³⁰ At the echo peak the magnetization is rephased as at the start of the FID. Now, however, the signal is separated from any interfering rf pulses so that it may be recorded accurately. Fourier transformation of the second half of the echo produces the spectral response.

A number of techniques reduce line broadening, allowing the extraction of spectral information by FT methods. Magic angle spinning (MAS), introduced by Andrew et al.³¹ and Lowe,³² can reduce the dipole–dipole contribution to the linewidths in solids.³³ Combining MAS with heteronuclear decoupling and cross polarization³⁴ (CP MAS) provides high resolution capabilities for dilute nuclear spins such as those of ¹³C.³⁵

Repetitive pulse sequences have also been developed. These effectively average interactions that normally cause broadening of lines in solids. The spin system is subjected to a repetitive sequence of closely spaced pulses. The spin response is digitized once per cycle of the sequence, thus building up the equivalent of a single FID which is then transformed in the usual way to produce a spectrum.³⁶

FT techniques have also been used in electron spin resonance (ESR), sometimes called electron paramagnetic resonance (EPR) spectroscopy. Generally, the electron FID signals are much shorter than the nuclear FID response found in liquids and solids; however, as the electronic equipment has improved, many of the multiple pulse and two-dimensional experiments commonly used in NMR have been applied to ESR.^{37,38}

FT techniques have been applied to many other forms of spectroscopy, such as ion cyclotron resonance (ICR) mass spectroscopy, nuclear quadrupole resonance (NQR), EPR,

dielectric spectroscopy, and microwave spectroscopy. Marshall has reviewed many of these techniques. The way in which FT methods have increased the sensitivity of these techniques is described below.³⁹

3 THE MATHEMATICS OF THE FOURIER TRANSFORM

There are a number of different mathematical formulations of the FT and the inverse transform.⁴⁰ One pair is given by the equations:

$$F(\nu) = \int_{-\infty}^{\infty} f(t) \exp(-i2\pi\nu t) dt \quad (1)$$

$$f(t) = \int_{-\infty}^{\infty} F(\nu) \exp(i2\pi\nu t) d\nu \quad (2)$$

where $i = \sqrt{-1}$, $f(t)$ is a function of time t , and $F(\nu)$ is a function of the frequency ν . The inverse transformation converts a frequency spectrum $F(\nu)$ back into the time domain $f(t)$.

The angular frequency $\omega = 2\pi\nu$ is often used for formal expressions yielding the transformation pair:

$$F(\omega) = \int_{-\infty}^{\infty} f(t) \exp(-i\omega t) dt \quad (3)$$

and

$$f(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} F(\omega) \exp(i\omega t) d\omega \quad (4)$$

Note that the expressions for $F(\omega)$ and $F(\nu)$ differ by 2π .

There are a number of properties or theorems that play a basic role in the application of FT pairs.⁴⁰ Some of the more useful ones are summarized below. By interchanging $F(\nu)$ and $f(t)$ and changing i to $-i$, the theorems also apply to the inverse transformations.

3.1 Similarity Theorem

If $f(t)$ has the FT $F(\nu)$, then $f(at)$ has the FT $|1/a|F(\nu/a)$.

This theorem illustrates that if the timescale is compressed by a factor of a ($a < 1$), the frequency scale expands by $1/a$, and, as it expands, the area of the spectrum remains constant.

3.2 Addition Theorem

If $f(t)$ and $g(t)$ have the FTs $F(\nu)$ and $G(\nu)$, respectively, then $f(t) + g(t)$ has the transform $F(\nu) + G(\nu)$.

This theorem illustrates that the FT transform is a linear transform and is suitable for dealing with linear problems. Although the NMR magnetization M does not respond linearly to the rf pulse, the subsequent FID motions are linear and the addition theorem applies.

3.3 Shift Theorem

If $f(t)$ has the FT $F(\nu)$, then $f(t - t_0)$ has the FT $\exp(-i2\pi \nu t_0) F(\nu)$.

This theorem illustrates that a change in the time origin of the FID causes a frequency-dependent phase change in the resulting spectrum. Modern NMR spectrometers can correct for frequency-dependent phase errors in the spectrum.

3.4 Convolution Theorem

If $H(\nu)$ represents the convolution of the two functions $F(\nu)$ and $G(\nu)$, then its FT $h(t)$ can be expressed as the product of the two functions $f(t)$ and $g(t)$ where they are the FTs of $F(\nu)$ and $G(\nu)$, respectively.

The convolution operator is expressed as:

$$\hat{H}(\nu) = F(\nu) * G(\nu) = \int_{-\infty}^{\infty} F(\mu) G(\nu - \mu) d\mu \quad (5)$$

and the corresponding relationship for the FT of these quantities is $h(t) = f(t)g(t)$. This theorem is extremely useful in any filtering process that makes use of convolution. To achieve the maximum possible signal-to-noise ratio, it is necessary to use a matched filter, which is determined by the lineshape. The FID of a Lorentzian spectral line with a relaxation time T_2 corresponds to a decay envelope given by $\exp(-t/T_2)$. Thus to obtain a spectrum with the best possible signal-to-noise ratio, the FID is multiplied by $\exp(-t/T_2)$ before the FT is taken.

Other filter applications that can make use of the convolution theorem include: resolution enhancement, to narrow artificially the resonance lines; lineshape transformations (for example, to transform the Lorentzian lines to Gaussian lines which cut off faster with frequency); apodization of the FID to suppress or eliminate oscillating signal tails in the spectrum; and correction of instrumental distortions, perhaps caused by the limited receiver bandwidth. These processes are trivial when done in the time domain, as compared to performing a convolution in the frequency domain.²³

3.5 Definite Integral

The definite integral of a function $F(\nu)$ from $-\infty$ to ∞ is equal to the value of its FT at the origin, $f(0)$.

$$f(0) = \int_{-\infty}^{\infty} F(\nu) d\nu \quad (6a)$$

$$F(0) = \int_{-\infty}^{\infty} f(t) dt \quad (6b)$$

This states that the initial value of a FID is equal to the area of its FT. With proper attention to the NMR phase adjustments, one can relate the initial value of the FID to the total area in the NMR spectrum.

3.6 Rayleigh's Theorem

The integral of the squared modulus of a function is equal to the integral of the squared modulus of its spectrum.

$$\begin{aligned} \int_{-\infty}^{\infty} |f(t)|^2 dt &= \int_{-\infty}^{\infty} f(t) f^*(t) dt = \int_{-\infty}^{\infty} F(\nu) F^*(\nu) d\nu \\ &= \int_{-\infty}^{\infty} |F(\nu)|^2 d\nu \end{aligned} \quad (7)$$

Here each integral represents the energy of the system. The term $|f(t)|^2$ has some interesting properties in that its value does not depend upon the origin or frequency offset of the transmitter.

3.7 The Sine and Cosine Transforms

The cosine transform $C(\nu)$ and sine transform $S(\nu)$ are obvious extensions of the standard FT:

$$C(\nu) = \int_{-\infty}^{\infty} f(t) \cos(2\pi \nu t) dt \quad (8a)$$

$$S(\nu) = \int_{-\infty}^{\infty} f(t) \sin(2\pi \nu t) dt \quad (8b)$$

It is useful to note that the cosine transform is symmetric about $\nu = 0$ and the sine transform is antisymmetric about $\nu = 0$. If $f(t)$ is real, then the real part of $F(\nu)$ is symmetric and the imaginary part antisymmetric about $\nu = 0$.

3.8 The Discrete Fourier Transform

For most NMR applications, the data have a finite time duration and are sampled and recorded at discrete time intervals. The discrete FT (DFT) is based on the use of periodic functions with period N so that $x(n) = x(n + kN)$, where n , N , and k are integers.^{40,41} The DFT is defined within the limited region of what would be one period of the periodic function. In contrast to Fourier series, which may have an infinite number of terms, there are only N distinct complex exponentials used in the DFT. The DFT and inverse transform can be written as:

$$F(\nu_k) = \sum_{n=0}^{N-1} f(t_n) \exp(-i2\pi kn/N) \quad (9)$$

$$f(t_n) = \frac{1}{N} \sum_{k=0}^{N-1} F(\nu_k) \exp(i2\pi kn/N) \quad (10)$$

The normalizing factor $1/N$ arises from the equality:

$$\sum_{n=0}^{N-1} \exp(i2\pi nk/N) = \begin{cases} N, & \text{for } k = mN, m \text{ an integer} \\ 0, & \text{otherwise} \end{cases} \quad (11)$$

In NMR, the FID signals are digitized at times $t_n = n\Delta\tau$, where $\Delta\tau$ is the time interval between successive analog-to-digital converter (ADC) samples, and n takes the N integer values from 0 to $N - 1$. The spectral frequencies ν_k measured in the rotating coordinate system extend from $-1/(2\Delta\tau)$ to $1/(2\Delta\tau)$, and have the values $\nu_k = k/(N \Delta\tau)$, where N is the total number of FID samples. In a single-channel system, k ranges from 0 to $N/2$, and in a quadrature system (discussed below) k ranges from $-N/2$ to $+N/2$. Modern computers and the fast FT (FFT) algorithms permit rapid computation of the DFT.^{43,44}

4 THE BLOCH EQUATIONS

The FT NMR experiments that use rf pulses for excitation are treated in greater detail here, since they are the ones in greatest use today. A FID signal is stimulated by applying a short rf magnetic field pulse at right angles to the constant polarizing magnetic field. Following the conventional notation, the polarizing magnetic field is along the z axis and the rf magnetic field along the x axis. By increasing the phase of the rf drive frequency by 90° , the effective axis of the rf field is changed to lie along the y axis. Thus roles of the x - and y -axes are easily interchanged, thereby permitting experiments where the effective rf field can be applied in any direction in the xy plane.

The phenomenological equations of Bloch⁵ and his development of the rotating coordinate system provide an easy way to describe the FT experiment and to resolve many questions regarding the optimization of experimental parameters. The equations in the laboratory system are:

$$\dot{M}_x = \gamma(M_y B_z - M_z B_y) - M_x/T_2 \quad (12a)$$

$$\dot{M}_y = \gamma(M_z B_x - M_x B_z) - M_y/T_2 \quad (12b)$$

$$\dot{M}_z = \gamma(M_x B_y - M_y B_x) - (M_z - M_0)/T_1 \quad (12c)$$

where M is the magnetization vector, $\dot{M}$ is the time derivative of M , and B is the applied magnetic field vector, with the subscripts indicating the particular components. With only a polarizing field B_z and no other magnetic field components, a solution of these equations is:

$$M_x = M_T \cos(\omega_0 t + \phi) \exp(-t/T_2) \quad (13)$$

$$M_y = M_T \sin(\omega_0 t + \phi) \exp(-t/T_2) \quad (14a)$$

$$M_z = M_0 + M_L \exp(-t/T_1) \quad (14b)$$

where $\omega_0 = -\gamma B_z$, and M_T is the total transverse magnetization. In a right-handed coordinate system, a positive value of γ yields a negative value of ω_0 . These equations describe a magnetization vector precessing about the magnetic field axis at an angular frequency of ω_0 , as shown in Figure 3. With the positive z axis taken in the direction of the magnetic field B_z , the sign of ω_0 is the same as the sign of $-\gamma$. The xy component of the magnetization decays toward zero with a time constant T_2 , and the z component of magnetization approaches M_0 with a time constant T_1 .

Figure 3 Precessing magnetization in the presence of a constant field B_z along the z axis

Using complex notation $f(t) = M^+ = M_x + iM_y = M_T \exp(i\omega_0 t + i\phi - t/T_2)$ and inserting it into equation (3) yields

$$\begin{aligned} F(\omega) &= M_T \exp(i\phi) \int_0^\infty \exp[i(\omega_0 - \omega)t - t/T_2] dt \\ &= M_T \exp(i\phi) \frac{1/T_2 + i(\omega_0 - \omega)}{(\omega_0 - \omega)^2 + (1/T_2)^2} \end{aligned} \quad (15)$$

Choosing the transverse magnetization M_T to be aligned along the x axis at time $t = 0$ corresponds to the phase $\phi = 0$. In this case the real part of $F(\omega)$ corresponds to the absorption signal $a(\Delta\omega)$, and the imaginary part corresponds to the dispersion signal $d(\Delta\omega)$ where

$$a(\Delta\omega) = M_T \frac{1/T_2}{(\Delta\omega)^2 + (1/T_2)^2} \quad (16a)$$

$$d(\Delta\omega) = M_T \frac{\Delta\omega}{(\Delta\omega)^2 + (1/T_2)^2} \quad (16b)$$

with the frequency offset $\Delta\omega = \omega_0 - \omega$.

4.1 The Rotating Coordinate Frame

The concept of the rotating coordinate frame can be helpful when visualizing the magnetization during the time for which an rf pulse is applied. In most FT experiments the pulse length τ is short compared with T_1 and T_2 so that, while the pulse is being applied, the terms in equations (12a)–(12c) containing T_1 and T_2 can be safely omitted. After the termination of the pulse, the solutions for the magnetization M are again given by equations (13), (14a) and (14b) with new values for M_T , M_L , and ϕ . It may be more useful to express the magnetization M in the rotating coordinate frame even after the termination of the pulse. In most spectrometer systems the signals are mixed with the transmitter frequency, so that the frequencies of the signals at the output of the mixer correspond to those of the rotating frame.

The rf pulse is normally described as a linearly oscillating field $2B_1 \cos(\omega_{rf}t + \psi)$. This field is equivalent to two counter-rotating fields, each with strength B_1 . Only the component that rotates in the same sense as the magnetization is effective in perturbing the nuclear spins. With $|B_1/B_z| \ll 1$ the counter-rotating component is safely ignored. Thus in the

Figure 4 Magnetization precession about the effective field $\mathbf{B}_{\text{eff}}$ in the coordinate frame with axes x' , y' and z' rotating with the rf field. The field $\mathbf{B}_{\text{eff}}$ is the vector sum of the rf field B_1 along the x' axis and the offset field $\Delta B_{z'}$ along the $z' = z$ axis

coordinate frame that rotates with the angular frequency ω_{rf} , the perturbing rf field has static components $B_{x'} = B_1 \cos \psi$ and $B_{y'} = B_1 \sin \phi$. By selecting the field $\Delta B_{z'} = B_z + \omega_{\text{rf}}/\gamma = -(\omega_0 - \omega_{\text{rf}})/\gamma$, the Bloch equations in the rotating system are identical to those of the static system. The solution to the equations is obvious. The magnetization in the rotating frame just precesses about the effective field of magnitude $B_{\text{eff}} = \sqrt{(\Delta B_{z'}^2 + B_1^2)}$ at the frequency $\omega' = -\gamma B_{\text{eff}}$, so that at the end of a pulse of length τ the magnetization $\mathbf{M}$ has been rotated through an angle $\beta = \gamma B_{\text{eff}} \tau$. The fields in the rotating coordinate system with $\phi = 0$ are illustrated in Figure 4.

If the rf frequency corresponds to the resonant frequency of the NMR line, then $\Delta B_{z'} = 0$ and the angle of rotation during an rf pulse $\beta = \gamma B_1 \tau$. If initially the magnetization is at equilibrium, that is directed along the z axis with $M_z = M_0$, then an rf pulse with $\beta = \pi/2$ (90° pulse) will rotate the magnetization from along the z axis to the xy plane ($z = 0$), resulting in the maximum FID signal. The FT of this signal produces a real and an imaginary output. By selecting a combination of these two outputs, one can display either the absorption or dispersion mode NMR lines.

To calculate the rotation of off-resonant lines, the magnetization is assumed initially to be aligned along the $z' = z$ axis. The rf field B_1 is along the x' axis, and the offset field $\Delta B_{z'}$ along the z' axis of the coordinate frame rotating at the angular frequency ω_{rf} . The total field in this rotating coordinate system is the vector addition of $\Delta B_{z'}$ and B_1 to yield $\mathbf{B}_{\text{eff}}$ along the z'' axis, which makes an angle θ with respect to the z' axis (Figure 4). During the rf pulse, the magnetization, initially along z' , rotates about z'' through an angle $\beta = -\gamma B_{\text{eff}} \tau$. At the end of the rf pulse the magnetization in this tilted rotating coordinate system has the following values, as can be deduced with the aid of Figure 4:

$$M_{x''} = -M_0 \sin \theta \cos \beta \quad (17a)$$

$$M_{y''} = M_0 \sin \theta \sin \beta \quad (17b)$$

$$M_{z''} = M_0 \cos \theta \quad (17c)$$

Figure 5 Plot of M_x , M_y , and M_T versus the normalized offset $[(\omega_0 - \omega_{\text{rf}})/(-\gamma B_1)] = \Delta B_{z'}/B_1$. At an offset $\Delta B_{z'} = B_1$, the magnetization M_x is decreased by over 40% while the total magnetization $M_T = \sqrt{(M_{x'})^2 + (M_{y'})^2}$ is decreased by about 2%

and expressing these values in the rotating coordinate frame yields:

$$M_{x'} = M_{x''} \cos \theta + M_{z''} \sin \theta = M_0 \sin \theta \cos \theta (1 - \cos \beta) \quad (18a)$$

$$M_{y'} = M_{y''} = M_0 \sin \theta \sin \beta \quad (18b)$$

$$M_{z'} = M_{z''} \cos \theta - M_{x''} \sin \theta = M_0 (\cos^2 \theta + \sin^2 \theta \cos \beta) \quad (18c)$$

The dependence of the signal amplitude as a function of the field offset $\Delta B_{z'}/B_1$ is shown in Figure 5. The field strength B_1 has been selected by letting $\gamma B_1 \tau = \pi/2$, so the NMR lines near the rf ω_{rf} produce the maximum amplitude. The in-phase signals M_y and the quadrature phase signals M_x are plotted. By tracking the phase adjustment over the spectrum, one can expect to obtain an absorption or dispersion signal equal to the total transverse amplitude of the magnetization M_T . The phase shift $\phi = \arctan(M_{x'}/M_{y'})$ and the total pulse rotation angle β are shown in Figure 6. It can be seen that a linear correction of the phase shift will compensate fairly closely for the frequency dependent phase shift over the frequency range comparable with the rf field strength $\gamma B_1/2\pi$.

As can be seen in Figure 5, the transverse magnetization vanishes when the normalized offset equals 3.87. Redfield and Gupta⁴⁵ proposed that strong solvent lines could be suppressed by adjusting their resonance to correspond to this offset. There are a number of composite pulse patterns that can be used for

Figure 6 The phase angle ϕ and nutation angle β versus the normalized offset $\Delta B_{z'}/B_1$

solvent suppression and to extend further the useful frequency range for a given pulse power.^{20,46}

5 THE FOURIER TRANSFORM SPECTROMETER ELECTRONICS

A block diagram of an early FT NMR spectrometer is shown in Figure 2. In this system the transmitter frequency is normally adjusted to be just beyond one edge of the NMR spectral region. After mixing, the received signal and transmitter frequency are sent through a bandpass filter and then digitized and stored in the digital memory of a computer. A complex DFT is performed to obtain the output spectrum. A phase adjustment that provides a means of selecting the proper ratio of real and imaginary outputs of the DFT enables one to obtain a pure absorption or dispersion mode spectrum.¹⁵

5.1 Required Pulse Power

For proton resonance the typical value of the rf pulse amplitude is 25 kHz (5.9×10^{-4} T) for 10 μ s to produce a 90° pulse. This takes a peak power of about 25 W at 600 MHz. This is sufficient to cover a spectrum width of about 25 kHz, which is quite adequate for proton spectra which have a spectral range of about 10 ppm. Carbon-13 is more of a problem with a spectral range of about 200 ppm and a smaller magnetic moment. At 14.1 T the width of the carbon spectral range is about 30 kHz, requiring a peak rf field strength of 28×10^{-4} T at 150 MHz. This takes a power of about 250 W at the 150 MHz operating frequency.

5.2 Quadrature System

The single-channel system suffers from several drawbacks that are overcome in dual channel or quadrature systems. One problem is that noise from both sides of the transmitter frequency is mixed with the signal frequency and contributes to the output noise. The quadrature system provides a $\sqrt{2}$ increase in sensitivity by eliminating the unwanted sideband noise. Another advantage is the more efficient use of rf pulse power gained by placing the rf at the center of the spectrum.⁴⁷ A block diagram of a quadrature system is shown in Figure 7.

The single sideband operation is obtained by splitting the receiver signals into two channels, and mixing one with a reference frequency that is in phase with the transmitter frequency, and mixing the other with a reference frequency in quadrature with the transmitter frequency.⁴⁷ After low-pass filtering, each of these two channels is digitized and stored in digital memory. The FT is applied separately to the signals in each of the two channels leading to four frequency domain signals. These can then be combined to select signals from either side of the transmitter frequency and, in addition, to display the desired absorption or dispersion mode spectrum (see Figure 7).

The low-pass filters are designed to cut out all frequencies greater than $1/(2\Delta\tau)$. The bandwidth of the system extends from $f_{\text{rf}} - 1/(2\Delta\tau)$ to $f_{\text{rf}} + 1/(2\Delta\tau)$. Any NMR signals, or noise that is generated outside of this frequency range, to

Figure 7 Block diagram of the electronics of an FT NMR spectrometer

the extent they are not filtered out by the low-pass filter, are present in the output. This process is called ‘aliasing’. Aliased signals can usually be detected by their different appearance since their higher frequency experiences a greater phase shift in the low-pass filter.

5.3 Phase Cycling

One problem that can occur in quadrature detection systems is the incomplete separation between the NMR signals on the two sides of the transmitter frequency. This can happen if the in-phase and quadrature phase channels are not adequately matched. The gains of the two channels must be nearly identical and the two mixers must receive reference signals that have a precise 90° phase difference. In the case of a mismatch, when the signals from the two channels are combined the cancellation of the unwanted sideband is not complete. Phase cycling of the transmitter frequency is a way to get around this problem. Phase cycling is done by shifting the transmitter phase by 90° on each successive readout pulse and routing the data with the correct sign to each of the four memory channels. After a first pulse the real and imaginary data of the *I* mixer go to memory locations 1 and 2, and the data of the *Q* mixer go to memory channels 3 and 4. The phase of the next transmitter pulse is increased by 90° and the roles of the *I* and *Q* mixers are interchanged. After this pulse, the data from mixer *I* go to memory channels 3 and 4, taking into account the correct sign, and similarly the data of mixer *Q* go to memory locations 1 and 2. During the third pulse, the transmitter phase is shifted by 180° compared with the first pulse, and the outputs of the *I* and *Q* mixers go to the same locations as in the first pulse, except for a sign change. After the fourth pulse, the routing configuration is identical to that of the first pulse.⁴⁸ This process has been called CYCLOPS by Hoult and Richards.⁴⁹ With suitable spectrometer programming the task can be performed automatically. After a sufficient number of phase cycles have been completed, the data are Fourier transformed and combined in the usual way to give the complete spectrum.

Figure 8 Simulated FID with $T_2 = 1$ s on the left and the corresponding FT on the right. (a) The full FID and its FT. (b) The FID truncated after 1 s and its FT. (c) The truncated FID, apodized with the function $\exp(-t/T)$ with $T = 0.33$ s, and its FT. In order to plot smoothed spectra, all FIDs were zero-filled before taking the FT

5.4 Digitization Rates and Number of Data Points

When taking the data, a choice must be made on the digitization rate $1/\Delta\tau$, and the total number of data points taken N . The Nyquist criterion relates the highest frequency at which nonredundant data occur in the spectrum. In a single-channel system the transmitter frequency is normally placed to one side of the NMR spectral region that is to be investigated, and so the output of the mixer contains signal frequencies from 0 to $0.5/\Delta\tau$. In a quadrature system, twice as many data points are obtained and the frequencies on the two sides of the transmitter frequency can be separated, giving spectral data from $-0.5/\Delta\tau$ to $+0.5/\Delta\tau$. The total time spent in obtaining the FID data $T = N\Delta\tau$ determines the density of data points in the spectrum. Stopping the data-taking process before the FID has decayed sufficiently produces 'truncation wiggles' in the spectrum (Figure 8). The truncation process is equivalent to multiplying a complete FID by a square wave of duration T . In the frequency domain this is equivalent to a convolution of the NMR spectrum with the spectrum of a square wave of width T . This problem can be avoided by taking more FID data points, N , by increasing $\Delta\tau$, or by applying a windowing function, as discussed in the next section.

5.5 Apodization Windows

To prevent a sharp discontinuity at the end of the FID, it can be multiplied by a window function that goes smoothly toward zero at the end of the FID. One such function is $\exp(-t_n/T^*)$. As mentioned above, a matched filter with the value $T^* = T_2$, goes at least part way and provides a reduction in truncation wiggles. Making T^* even smaller will further reduce the truncation wiggles; however, there is a penalty of some loss in resolution. The smoothing and loss of resolution is apparent in the illustration at the bottom of Figure 8. Another common window function is the Hanning apodization which has the form $h(t_n) = 0.5[1 + \cos(\pi t_n/T)]$. Apodization may

be combined with resolution enhancement by using a function such as $0.5[1 + \cos(\pi t_n/T)]\exp(2\pi t_n/T_2)$. A number of other window functions have been used.²³

5.6 Zero Filling

As was mentioned above, by extending the time used to record the FID, the resolution can be improved at the expense the signal-to-noise ratio. Extending the data collection of the FID after it has decayed nearly to zero will increase the noise contribution more than the signal contribution. Zero filling is the process of inserting zeros in the data field at the end of the FID in order to extend artificially the duration T . With N real FID data points one obtains $N/2$ independent complex Fourier coefficients. In general, the real and imaginary data points in the spectrum are independent. Because of causality and a Hilbert transform relationship (sometimes called the 'Kramers-Krönig relationship') between the absorption and dispersion mode signals, one can obtain N absorption data points and N dispersion data points where now each contains the full information available from the FID. Bartholdi and Ernst⁵⁰ have shown that this can be achieved by appending N zeros to the FID data field before making the FT. Appending $(2n - 1)N$ zeros to the FID, with $n > 1$, will provide an additional interpolation of points in the spectrum, thus giving a spectrum which looks smoother but contains no further information.

5.7 Linear Prediction

It may be necessary or desirable to truncate the FID before it has substantially decayed, leading to truncation wiggles. Another problem is that it may not be possible to obtain the first few data points of an FID due to the dead time of the receiver or some other reason. Linear prediction is a process that extrapolates the data already contained in the FID in order to obtain a best guess of points beyond the range of the data, either before the first data point or after the last data point. The FID can be modeled using an arbitrary number of exponentially decaying sinusoidal waves to represent the contributions from the various NMR lines. Each line can be represented by an initial amplitude, decay time constant, frequency, and phase. After determining the best fit to the model, the model can be used to calculate additional points that may be missing before the start of the FID data or beyond the end of the truncated FID. The technique has been particularly useful in straightening out the baseline of a spectrum that was made from a delayed acquisition of the FID. It can also be used for resolution enhancement and smoothing of the data.⁵¹

The maximum entropy method is sometimes used to obtain the best fit of data to amplitude and frequency parameters. This method of fitting the data to a model has shown encouraging results; however, the lengthy computation required has prevented its wide acceptance.⁵²

1 INTRODUCTION

These days the acquisition of a proton decoupled carbon-13 spectrum is relatively straightforward; however, the interpretation of the spectrum is often much more challenging. Fortunately, there are a variety of heteronuclear assignment techniques which are available to help with this task. Aside from deductions based upon chemical shifts and relaxation properties, the most common assignment technique involves the transfer of magnetization between nuclei via spin coupling, a process often referred to as coherence transfer.

There are basically two methods of transferring magnetization between nuclei, either free precession or forced precession. In both these processes, a time (τ) is chosen which is related to the reciprocal of a coupling constant. In the former method, pulses are applied separated by a delay τ during which the transmitter is turned off. In the latter method, pulses are applied for a total time τ . Thus, the difference between the two techniques is whether the transmitter is left on, or turned off for the time τ . In the past, heteronuclear assignment techniques relied almost exclusively on the former method, i.e. combinations of pulses and delays. However, the latter method, coherence transfer in the rotating frame via multiple pulse based heteronuclear J cross polarization, also known as hetero-TOCSY, has become increasingly popular.

2 MULTIPLICITY DETERMINATION

Most heteronuclear spectra are acquired with broadband proton decoupling. Despite this, it is often desirable to determine the multiplicity, or number of directly attached protons. In theory, this information could be obtained from a proton coupled spectrum; however, in practice, this is often inconvenient because of spectral overlap and low sensitivity. Therefore, experiments have been developed which encode multiplicity information into broadband decoupled spectra. This process is often referred to as spectral editing.

2.1 APT

The attached proton test (APT) interrupts the decoupling for a time (τ) between excitation and detection. The delay

τ is related to the reciprocal of an appropriate heteronuclear coupling constant, usually $^1J(\text{C,H})$. During the period τ the different components of the proton coupled multiplets precess at their individual frequencies, which are governed by their heteronuclear J coupling. The recombination of these components, when the decoupler is turned back on, produces a constructive or destructive interference. The signals from methine and methyl carbons appear inverted with respect to those from quaternary and methylene carbons. However, the use of this simple sequence leads to a severe frequency dependent phase shift across the spectrum, which is normally unacceptable. This phase shift can be removed by the use of a spin echo. The echoes can be modulated by either gating the decoupler,^{1–3} or by use of a 180° proton pulse synchronized with the 180° carbon pulse.⁴ The two methods, shown in Figure 1, are referred to as the gated decoupler and proton flip techniques by analogy to heteronuclear two-dimensional J spectroscopy.⁵ The gated decoupler method is normally used; however, the proton flip method is more interesting because it can be seen, conceptually, as a step toward the SEMUT (subspectral editing using a multiple quantum trap) experiment.

Semiclassical vector models are often used to explain echo sequences.⁶ However, it is necessary to use the product operator formalism here, because of the importance of techniques based upon the generation of multiple quantum coherence. The product operator approach uses a form of shorthand algebra to follow the spin gymnastics.^{7,8} Let us start with a step-by-step analysis of the product operator transformations associated with the proton flip version of the attached proton test shown in Figure 1(b), for a $^{13}\text{C}, ^1\text{H}$ spin system. For simplicity only terms that contribute to the final spectrum are shown. The first step is a 90° excitation pulse acting on the z magnetization of the carbons; thus equation (1) contains an operator representing the state of the magnetization (in this case, the carbon magnetization at thermal equilibrium; $\hat{C}_z$) which is acted upon by a rotation operator (in this case, a

Figure 1 Basic echo sequences for heteronuclear multiplicity selection (APT). (a) Gated decoupler method; (b) spin flip method. τ is set to $1/J$ for an even/odd subspectrum. In this, and subsequent, diagrams the phase of all 180° pulses is of no practical importance, apart from the necessity of inverting the receiver reference phase if the phase of a 180° pulse is changed by 90°

2 HETERONUCLEAR ASSIGNMENT TECHNIQUES

rotation of the carbon magnetization about the x axis; $\hat{C}_x$):

$$\hat{C}_z \xrightarrow{(\pi/2)\hat{C}_x} -\hat{C}_y \quad (1)$$

Heteronuclear spin coupling evolves during the subsequent delay τ . The operator for spin-spin coupling is represented by $2\hat{C}_z\hat{H}_z$, that is, a rotation about the z axis for both nuclei, leading to the following:

$$-\hat{C}_y \xrightarrow{(\pi J_{CH}\tau)2\hat{C}_z\hat{H}_z} -\hat{C}_y \cos(\pi J_{CH}\tau) + 2\hat{C}_x\hat{H}_z \sin(\pi J_{CH}\tau) \quad (2)$$

If the interval τ is chosen such that $\tau = 1/(2J_{CH})$ then the cosine term becomes zero and we are left with:

$$-\hat{C}_y \xrightarrow{(\pi/2)2\hat{C}_z\hat{H}_z} +2\hat{C}_x\hat{H}_z \quad (3)$$

that is to say, two carbon magnetization vectors aligned in opposition along the $\pm x$ axes. We can ignore the simultaneous 180° pulses on both spins because they have the same effect as a single 180° pulse in a homonuclear spin system, i.e. they refocus the chemical shift while having no effect upon either homo- or heteronuclear coupling. After a further delay $\tau = 1/(2J_{CH})$ we find the two vectors are realigned again, but along the $+y$ rather than the $-y$ axis:

$$+2\hat{C}_x\hat{H}_z \xrightarrow{(\pi/2)2\hat{C}_z\hat{H}_z} \hat{C}_y \quad (4)$$

For an odd multiplicity (e.g. CH and CH_3) we can summarize this whole process as

$$\hat{C}_z \xrightarrow{(\pi/2)\hat{C}_x} -\hat{C}_y \xrightarrow{(\pi/2)2\hat{C}_z\hat{H}_z} 2\hat{C}_x\hat{H}_z \xrightarrow{(\pi/2)2\hat{C}_z\hat{H}_z} \hat{C}_y \quad (5)$$

Whereas for an even multiplicity (e.g. CH_2) these transformations become

$$\hat{C}_z \xrightarrow{(\pi/2)\hat{C}_x} -\hat{C}_y \xrightarrow{(\pi/2)2\hat{C}_z\hat{H}_z} 2\hat{C}_y\hat{H}_z \xrightarrow{(\pi/2)2\hat{C}_z\hat{H}_z} -\hat{C}_y \quad (6)$$

Notice that in the second case the magnetization passes through a magnetization state represented by the operator $2\hat{C}_y\hat{H}_z$ rather than $2\hat{C}_x\hat{H}_z$. This leads to a pairwise separation of multiplicities. Improved J compensated APT experiments have been proposed, which reduce the problems of cross-talk between the spectra due to the inevitable spread in the values of the coupling constants.⁹

2.2 SEMUT

The major disadvantage with APT is that the spectra are sorted only on the basis of even or odd multiplicity; thus, methine and methyl carbons are indistinguishable. In practice, it is more convenient to produce subspectra containing each multiplicity separately. The SEMUT pulse sequence, which is set out in Figure 2, is superior to APT in these regards.¹⁰

Let us follow the product operator transformations which take place during SEMUT. They take the following form when

Figure 2 SEMUT pulse sequence; τ is set to $1/(2J)$

the multiplicity (n) is odd (e.g. CH_3 and CH), $\tau = 1/(2J_{CH})$ and the flip angle of the proton pulse is θ :

$$\begin{aligned} \hat{C}_z &\xrightarrow{(\pi/2)\hat{C}_x} -\hat{C}_y \xrightarrow{(\pi/2)2\hat{C}_z\hat{H}_z} 2\hat{C}_x\hat{H}_z \xrightarrow{(\theta/2\pi)\hat{H}_x, (\pi)\hat{C}_x} 2\hat{C}_x\hat{H}_z \cos^n \theta \\ &\xrightarrow{(\pi/2)2\hat{C}_z\hat{H}_z} \hat{C}_y \cos^n \theta \end{aligned} \quad (7)$$

When n is even, the product operator takes the same form at the end of the sequence, despite the fact that the magnetization passes through a state of $2\hat{C}_y\hat{H}_z$. In both cases, the spectra are edited as a function of $\cos^n \theta$. That is, the flip angle dependence for the individual CH_n intensities, $I(\text{CH}_n)$, may be written as

$$I(\text{C}) = 1 \quad (8)$$

$$I(\text{CH}) = \cos \theta \quad (9)$$

$$I(\text{CH}_2) = \cos^2 \theta \quad (10)$$

$$I(\text{CH}_3) = \cos^3 \theta \quad (11)$$

In practice, four different spectra are acquired with different flip angles θ , e.g. $\theta = 0^\circ$, $\theta = 60^\circ$, $\theta = 120^\circ$, and $\theta = 180^\circ$. These are combined in various proportions to produce the final C, CH, CH_2 , and CH_3 subspectra. The precision of the editing procedure has been improved in the SEMUT GL sequence¹¹ by the introduction of a purging sandwich ($90^\circ - \tau/2 - 180^\circ - \tau/2 - 90^\circ$). A further modification is that the various delays need not be equal.

2.3 INEPT

The INEPT (see *INEPT*) was originally designed to improve the sensitivity of proton coupled heteronuclear spectra.¹² However, a modification of INEPT was later shown to be capable of multiplicity selection.¹³ The pulse sequence for INEPT is set out in Figure 3. The first pulse, a 90° proton pulse about the $+x$ axis, generates transverse proton magnetization. During the following period $1/4J - 180^\circ(\text{H,C}) - 1/4J$, the heteronuclear coupling (J_{CH}) evolves, while the chemical shifts of both nuclei are refocused. This produces two proton magnetization vectors aligned in opposition along the $\pm x$ axes. If a 90° pulse is applied to the protons about the $+y$ axis, longitudinal two-spin order is created, often represented by proton spin vectors aligned along the $\pm z$ axes. These population disturbances affect the carbon magnetization because

Figure 3 INEPT pulse sequence. To eliminate undesired contributions from the native ^{13}C spin magnetization, the second ^1H 90° should be alternately applied along the $+y$ and $-y$ axes, combined with inversion of the receiver reference phase

of their common energy levels and can be studied by a 90° pulse applied to the carbons. This process can be summarized as

$$\begin{aligned} \hat{H}_z &\xrightarrow{(\pi/2)\hat{H}_x} -\hat{H}_y \xrightarrow{(\pi/2)2\hat{H}_z\hat{C}_z} 2\hat{H}_x\hat{C}_z \xrightarrow{(\pi/2)\hat{H}_y} -2\hat{H}_z\hat{C}_z \\ &\xrightarrow{(\pi/2)\hat{C}_x} 2\hat{H}_z\hat{C}_y \end{aligned} \quad (12)$$

Proton-coupled spectra are obtained, but multiplets do not display the normal intensity distribution, because the magnetization is detected in the form $2\hat{H}_z\hat{C}_y$; thus doublets appear as $+1, -1$, triplets $+1, 0, -1$, and quartets $+1, +1, -1, -1$.

In order to decouple such multiplets, a delay must be added in order to allow the various components of the multiplet to interfere constructively. The length of this delay is related to both J and the multiplicity. At the center of the delay, 180° pulses are applied to both nuclei, to minimize off-resonant effects.¹³ This sequence, shown in Figure 4, has been called refocused INEPT. If only a single proton is attached to each carbon then the condition for optimum signal strength is $\tau_2 = 1/4J$. However, when signals with varying multiplicities are present, a compromise value of $\tau_2 = 1/6J$ can be used which treats all multiplicities approximately equally. Alternatively, three separate spectra can be acquired with different values of τ_2 , such as $\tau_2 = 1/8J$, $\tau_2 = 1/4J$, and $\tau_2 = 3/8J$, which can be used to disentangle the various multiplicities.

Figure 4 Refocused INEPT pulse sequence; τ_2 varies with the multiplicity of the signal to be decoupled. See text for details

Refocused INEPT has been modified to yield INEPT⁺.¹⁴ This improvement concerns the addition of a 90°_x purging pulse immediately before data acquisition so that multiplets with the normal binomial distribution pattern are obtained if the spectra are not decoupled. The INEPT⁺ sequence is shown in Figure 5.

Figure 5 INEPT⁺ pulse sequence; τ_2 is set as in refocused INEPT

Figure 6 DEPT pulse sequence

2.4 DEPT

The DEPT experiment¹⁵ resembles an early heteronuclear multiple quantum coherence experiment.¹⁶ It has been widely adopted as a method of multiplicity selection because it is much less sensitive to J cross-talk than refocused INEPT. However, as a method of sensitivity enhancement it has the disadvantage that it takes three times longer than the basic INEPT sequence. The pulse sequence is set out in Figure 6.

Let us analyze the DEPT sequence for a CH group. Since the two 180° pulses serve only to refocus the chemical shift, we can ignore them in the following discussion, as well as the evolution of the chemical shift:

$$\begin{aligned} \hat{H}_z &\xrightarrow{(\pi/2)\hat{H}_x} -\hat{H}_y \xrightarrow{(\pi/2)2\hat{H}_z\hat{C}_z} 2\hat{H}_x\hat{C}_z \xrightarrow{(\pi/2)\hat{C}_x} -2\hat{H}_x\hat{C}_y \\ &\xrightarrow{(\pi/2)2\hat{H}_z\hat{C}_z} -2\hat{H}_x\hat{C}_y \xrightarrow{(\theta/2\pi)\hat{H}_y} 2\hat{H}_z\hat{C}_y \sin \theta \\ &\xrightarrow{(\pi/2)2\hat{H}_z\hat{C}_z} -\hat{C}_x \sin \theta \end{aligned} \quad (13)$$

The editing function is, to a first approximation, dependent only upon the flip angle θ , i.e. it does not depend upon J , which accounts for the superiority of DEPT over refocused INEPT as a method of multiplicity determination. Further improvements in spectral editing can be obtained with the DEPT-GL sequence.¹¹

In general, multiplicity selection, or spectral editing, can be thought of as a kind of building block, which can be added to other techniques. For example, multiplicity selection has been applied to HMQC,¹⁷ HSQC,¹⁸ and hetero-TOCSY¹⁹ experiments.

3 HETERONUCLEAR CHEMICAL SHIFT CORRELATION

Heteronuclear chemical shift correlation can involve either direct or indirect detection of the heteronucleus. Indirect

4 HETERONUCLEAR ASSIGNMENT TECHNIQUES

detection offers a sensitivity advantage of $\gamma^{3/2}$ compared with direct heteronuclear correlation. This means a sensitivity advantage of a factor of eight per transient in a ^1H detected ^{13}C correlation experiment, or 30 for ^1H detected ^{15}N correlation. For historical reasons, we start by discussing direct detection.

3.1 2D INEPT and 2D DEPT

It is useful to think of INEPT and DEPT as precursors of 2D heteronuclear chemical shift correlation experiments, despite the fact that this reverses the true chronology. The corresponding 2D experiments are formed by the introduction of an evolution period after the initial 90° pulse. Removing the heteronuclear coupling in F_1 is accomplished by the addition of a 180° pulse on the heteronucleus at the middle of the evolution time. The expansion of INEPT into a 2D experiment is shown in Figure 7.^{20,21}

Figure 7 2D INEPT pulse sequence for heteronuclear chemical shift correlation; τ_1 is set to $1/(2J)$ while τ_2 is often set to a compromise value of $1/(3J)$. The spectra are normally displayed in the magnitude mode to avoid the problems of phase correction

Figure 8 shows the corresponding 2D DEPT experiment.²² The 2D DEPT experiment is fully refocused, and therefore requires less frequency dependent phase correction. It also allows multiplicity determination because the correlations from CH and CH_3 moieties appear with the opposite phase to those from CH_2 moieties. Both these factors mean that 2D DEPT is probably preferable to 2D INEPT for phase sensitive work with small molecules, despite the fact that 2D DEPT is 50% longer.²³

3.2 COLOC

2D INEPT or 2D DEPT was designed to utilize the large direct (one bond) coupling constant for the heteronuclear coherence transfer. While it is possible to use these sequences

Figure 8 2D DEPT pulse sequence. Phase sensitive displays are often used which enable even/odd multiplicity determination

Figure 9 COLOC pulse sequence for heteronuclear chemical shift correlation through multiple bonds

for the study of long-range (multiple bond) heteronuclear correlation, it is preferable to use a sequence designed to incorporate a constant value of the evolution time,²⁴ because there is considerable loss of magnetization due to proton relaxation during t_1 and the delay τ_1 , as well as carbon relaxation during the delay τ_2 . In so-called ‘constant time’ experiments the evolution time is placed inside the τ_1 delay, as shown in Figure 9. This reduces the total time during which proton transverse relaxation takes place. The most popular technique is called COLOC,²⁵ although a variety of other sequences have been proposed.^{26,27}

3.3 Relay

If a homonuclear correlation step is inserted into a heteronuclear correlation experiment we arrive at the sequence shown in Figure 10 which can be described as a proton relayed heteronuclear correlation experiment.²⁸ Additional signals, so-called ‘relayed’ peaks, appear in the spectrum which provide indirect information on connectivity of the heteronuclei. The 2D spectrum has the heteronuclear chemical shift on one axis, with signals from the directly bonded protons and protons to which they are coupled, for example their $^3J(\text{HCCH})$ neighbors, along the other axis. Thus, the relay experiment provides complementary data to a long-range heteronuclear correlation experiment.

After proton evolution with heterodecoupling, a homonuclear transfer takes place from one proton to other protons which are spin coupled to it. The evolution of the proton chemical shift is refocused during this transfer by the first proton 180° pulse. It is also desirable to refocus the proton chemical shift during the subsequent heteronuclear transfer. This leads to a sequence with two adjacent 180° proton pulses, as shown in Figure 10. However, this can be simplified because it is

Figure 10 Proton relayed heteronuclear chemical shift correlation sequence

Figure 11 Optimized proton relayed heteronuclear chemical shift correlation sequence

Figure 12 Carbon relayed heteronuclear chemical shift correlation sequence

often possible to concatenate 180° pulses; thus the two adjacent proton 180° pulses can be replaced by a single one in the middle of the delays $2\tau_1$ and $2\tau_2$ without changing the net effect,^{29–31} as shown in Figure 11. The reverse experiment is also possible, that is, to relay the magnetization via the heteronucleus, as shown in Figure 12.³²

3.4 Indirect Detection

Indirect detection has become the standard method of performing heteronuclear correlation. Both single or multiple quantum correlation techniques are in use. The heteronuclear multiple quantum experiments are derivatives of experiments originally proposed by Müller.¹⁶ Most of the heteronuclear single quantum experiments are variations of a double INEPT experiment first proposed by Bodenhausen and Ruben.³³ It can be shown, both theoretically and practically, that experiments involving single quantum correlation have several advantages.^{34,35}

3.5 HMQC

Heteronuclear multiple quantum correlation (HMQC) was initially very popular as a method of performing indirect detection experiments.³⁶ The HMQC pulse sequence is shown in Figure 13. For a heteronuclear H–C system, the experiment can be described as

$$\begin{aligned} \hat{H}_z &\xrightarrow{(\pi/2)\hat{H}_x} -\hat{H}_y \xrightarrow{(\pi/2)2\hat{H}_z\hat{C}_z} -2\hat{H}_x\hat{C}_z \xrightarrow{(\pi/2)\hat{C}_x} -2\hat{H}_x\hat{C}_y \\ &\xrightarrow{t_1} -2\hat{H}_x\hat{C}_y \cos \Omega_c t_1 \xrightarrow{(\pi/2)\hat{C}_x} -2\hat{H}_x\hat{C}_z \cos \Omega_c t_1 \quad (14) \end{aligned}$$

where Ω_c denotes the angular offset frequency of the carbon spin. The above expression predicts that the detected in-phase ^1H signal (H_y) is modulated in amplitude by Ω_c , giving

Figure 13 HMQC pulse sequence for ^1H detected heteronuclear chemical shift correlation utilizing heteronuclear multiple quantum coherence during the evolution period

rise to a single absorptive correlation in the 2D spectrum. Unfortunately this is not the whole story. Additional protons have an important effect. Consider an I–K–S spin system (where both I, K = ^1H , S = ^{13}C or ^{15}N), that is, the effect of a second proton K. The relatively small homonuclear coupling J_{IK} can safely be neglected during the delay τ . However, it cannot be neglected during the evolution time. Consequently the magnetization at the beginning of the detection period can be summarized as

$$-\hat{I}_y \cos \pi J_{IK} t_1 \cos \Omega_s t_1 + 2\hat{I}_x \hat{K}_z \sin \pi J_{IK} t_1 \cos \Omega_s t_1 \quad (15)$$

The multiplet pattern resembles that of a 2D J spectrum, in that it is phase modulated in t_1 . Thus, it is impossible to obtain pure phases. Another disadvantage of HMQC is that the spectrum will display homonuclear J coupling in the F_1 dimension. There is yet another problem with the resolving power of HMQC, in that the linewidth in the F_1 dimension is determined by the relaxation rate of the multiple quantum coherence $\hat{H}_x\hat{C}_y$. This often leads to broadening, since multiple quanta usually relax faster than single quanta.^{34,35}

Quite a few modifications to the basic HMQC sequence have been proposed.^{37–40} For example, it is often desirable to perform heteronuclear correlation without presaturation of the water signal. One method of achieving this is to replace the 90° and 180° ^1H pulses with jump-and-return pulses as shown in Figure 14.⁴¹

The suppression of spurious signals which originate from protons not bonded to the heteronucleus can be improved in a variety of ways. The most common of these is to precede HMQC by a so-called BIRD (bilinear rotational decoupling) sequence as shown in Figure 15.⁴² The BIRD sequence inverts the z magnetization of protons attached to ^{12}C while leaving the magnetization of the protons attached to ^{13}C unaffected. A relaxation delay is added between the BIRD and the start of the HMQC sequence, in a manner reminiscent of WEFT.⁴³ The idea is to use differential relaxation as a method of improving the suppression of the unwanted signals from ^{12}C . Since ^{13}C has a spin, protons attached to ^{13}C will relax faster than those attached to ^{12}C . Thus, it may be possible to choose a delay

Figure 14 HMQC correlation in H_2O without presaturation

Figure 15 HMQC pulse sequence with BIRD presaturation of protons coupled to ^{12}C

such that the signal from all the protons attached to ^{12}C are approximately nulled, while all the protons attached to ^{13}C have relaxed. However, this method is unattractive for large molecules because they often exhibit a negative NOE, in which case, cross relaxation between the inverted protons attached to ^{12}C and the noninverted protons attached to ^{13}C will decrease the signal intensity.

3.6 Flip-back

An alternative approach, which avoids the problem of sensitivity loss by cross relaxation, is to refocus the magnetization of the protons attached to ^{12}C prior to the evolution period.¹⁶ The in-phase magnetization from the protons attached to ^{12}C can then be flipped back to the $+z$ axis while the heteronuclear antiphase magnetization is unaffected. The sequence is shown in Figure 16. The sequence starts with $90^\circ_x(^1\text{H})-1/(4J)-180^\circ(^1\text{H},^{13}\text{C})-1/(4J)-$, where the simultaneous 180° pulses refocus chemical shift evolution. At the end of this period, all protons coupled to the heteronucleus are antiphase ($\hat{I}_x\hat{S}_z$) with respect to the heteronuclear coupling. Since the proton homonuclear coupling constants $J(\text{H}, \text{H})$ are usually much smaller than $^1J(\text{C}, \text{H})$, all protons attached to ^{12}C still have essentially only in-phase magnetization (I_y). This allows a separation of protons attached to ^{12}C and ^{13}C by the action of a $90^\circ_x(^1\text{H})$ pulse at the end of the preparation period. The $90^\circ_x(^1\text{H})$ pulse flips the in-phase ^1H magnetization I_y of the protons attached to ^{12}C to the $-z$ axis while the antiphase I_xS_z remains unaffected. However, at the same time the $90^\circ_x(^{13}\text{C})$ converts the antiphase magnetization, I_xS_z , into heteronuclear two-spin coherence I_xS_y , which evolves during t_1 . The 180° pulse at the midpoint of the evolution time interchanges the zero and double quantum frequencies. Not only does this eliminate the ^1H chemical shift component from the multiple quantum frequency, as in HMQC, but it also it flips the protons attached to ^{12}C back to the $+z$ axis. Cross relaxation then causes the rapid recovery of the longitudinal magnetization of the protons attached to ^{13}C .

Figure 16 Flip-back chemical shift correlation

Figure 17 HMBC pulse sequence for ^1H detected heteronuclear multiple bond correlation utilizing heteronuclear multiple quantum coherence during the evolution period. The first ^{13}C 90° serves as a low-pass J filter. The spectra are normally displayed in the magnitude mode to avoid the problems of phase correction

Unfortunately, this modification is unsuitable if ^{13}C decoupling is desired during data acquisition, because the ^1H chemical shifts are in-phase at the end of the evolution period, whereas the decoupling should be started at a time $1/(2J_{\text{CH}})$ later.

3.7 HMBC

A simple extension of the HMQC experiment can be used to determine long range (two and three bond) correlations. It is convenient to add a low-pass J filter, to suppress the direct one bond correlations.⁴⁴ The resulting HMBC sequence is shown in Figure 17.⁴⁵

Many applications of indirect detection focus on nuclei such as ^{13}C and ^{15}N ; however, other interesting applications of long-range heteronuclear correlation techniques concern the indirect detection of phosphorus. In these cases, where the T_1 of the heteronucleus is shorter than the T_1 of the protons but its T_2 is longer than that of the protons, a different approach may be preferable.⁴⁶

3.8 HSQC

The heteronuclear single quantum correlation experiment has become increasingly popular in recent years.³³ The pulse sequence is set out in Figure 18. This experiment employs an INEPT sequence¹² to transfer proton z magnetization into antiphase nitrogen magnetization. Proton decoupling during the evolution time is accomplished with a 180° proton pulse at the midpoint of the evolution time. A subsequent reverse INEPT transfer reconverts the transverse ^{13}C magnetization into observable ^1H magnetization. This can be summarized as

$$\begin{aligned} \hat{H}_z &\xrightarrow{\text{INEPT}} -2\hat{H}_z\hat{C}_y \xrightarrow{t_1} -2\hat{H}_z\hat{C}_y \cos \Omega_c t_1 \\ &\xrightarrow{\text{reverseINEPT}} -\hat{H}_x \cos \Omega_c t_1 \end{aligned} \quad (16)$$

The 2D spectrum displays neither $^1\text{H}-^1\text{H}$ nor $^1\text{H}-^{13}\text{C}$ spin coupling in the F_1 dimension. However, $^{13}\text{C}-^{13}\text{C}$ spin coupling is active in the F_1 dimension, but this will normally only be visible in isotopically enriched samples. The transverse relaxation rate of $\hat{H}_z\hat{C}_y$ corresponds to the sum of the relaxation rate of $\hat{C}_y$, i.e. the reciprocal of the ^{13}C T_2 , and the longitudinal relaxation rate of $\hat{H}_z$. This latter contribution is often described as scalar relaxation of the

Figure 18 HSQC pulse sequence (sometimes known as the Overhauser correlation experiment) utilizing heteronuclear single quantum coherence during the evolution time, and a 180° ^1H pulse to remove the net effect of heteronuclear coupling

Figure 19 Constant time HSQC pulse sequence for heteronuclear correlation of isotopically enriched species

second kind.⁴⁷ Whenever H_z changes its spin state, the ^{13}C doublet component changes its frequency by $J(\text{C}, \text{H})$, therefore the F_1 linewidth corresponds to the ^{13}C linewidth in a ^1H coupled ^{13}C spectrum.

There are two major modifications to the HSQC experiment. They both pertain to resolution enhancement. Firstly, the constant time HSQC experiment shown in Figure 19 removes the effects of ^{13}C – ^{13}C coupling in the F_1 dimension.^{48–50} Secondly, much narrower lines can be obtained by decoupling during the evolution time as shown in Figure 20.³⁵

3.9 Inverse Relay

Since relay experiments involve a combination of a heteronuclear and a homonuclear correlation step, i.e. a combination of two separate 2D experiments, they are particularly suitable for the application of 3D spectroscopy. In the past, the relay step was performed by pulsed methods; however, it is now more common to use TOCSY for this purpose. We examine two examples here, that of 2D HMQC–TOCSY⁵¹ and 3D TOCSY–HMQC.⁵² The 2D HMQC–TOCSY sequence is shown in Figure 21. The sequence combines HMQC and TOCSY in a straightforward manner. At the beginning of the TOCSY mixing step, the ^1H magnetization is aligned along the y axis and modulated in

Figure 20 Decoupled HSQC pulse sequence utilizing a composite pulse decoupling scheme preceded by a refocusing interval

Figure 21 2D HMQC–TOCSY pulse sequence

Figure 22 3D TOCSY–HMQC pulse sequence

amplitude by the heteronuclear chemical shift. The TOCSY mixing scheme then redistributes the magnetization of the heteronuclear coupled proton over all its coupling partners. So, in the final 2D spectrum, all coupled protons will be modulated by the frequency of the heteronucleus. A 3D version of the opposite combination is shown in Figure 22.

3D ^1H – ^{15}N TOCSY–HMQC spectra can be used to identify spin systems in macromolecules, such as proteins.⁵³ The idea is to correlate the NH ^1H and ^{15}N chemical shifts of each amino acid residue with the corresponding C- α ^1H chemical shifts. The first step of this process is to allow the aliphatic ^1H chemical shifts to evolve during the period t_1 . The magnetization of the aliphatic protons is transferred by TOCSY to the corresponding intrareidue NH protons. Subsequently the NH ^1H magnetization is transferred to the directly bonded ^{15}N spins by HMQC. A 3D ^1H – ^{15}N TOCSY–HMQC spectrum has the appearance of a regular 2D TOCSY spectrum apart from the fact that the signals are spread out over a series of slices edited by the ^{15}N chemical shifts.

3.10 Hetero-TOCSY

Since its first description by Hartmann and Hahn,⁵⁴ coherence transfer in the rotating frame has found wide application as a method of improving the repetition rate in solid state experiments. Although the possibility of using heteronuclear cross polarization as a method of chemical shift correlation in liquids was recognized and demonstrated long ago,^{55,56} technical problems have prevented its widespread use. The solution to many of these problems has appeared as a byproduct of the interest generated by homonuclear cross polarization, otherwise known as TOCSY.⁵⁷

Cross polarization experiments are normally carried out by applying a 90° pulse to one of the spins, followed by simultaneously spin locking both nuclei. When these spin lock fields are larger than the chemical shift, the Hamiltonian reduces to the spin–spin interaction terms, which are dipolar in origin for solids and scalar for isotropic liquids. Cross polarization occurs when the effective secondary nutation frequency of both rotating frames is the same. This is referred to as the Hartmann–Hahn condition, and has to be matched

better than the interaction frequency between the spins.⁵⁸ This is easy in solids where the large dipolar fields constitute the interaction between the spins. However, in isotropic liquids, the interaction is spin–spin coupling, giving rise to the name *J* cross polarization. The one bond coupling between ¹³C and ¹H is about 140 Hz, while rf fields of the order of 10 kHz are necessary to excite the nuclei evenly. Thus, in liquids the rf amplitudes need to be matched to better than 1%, which renders the experiment technically very demanding. However, the simultaneous use of multiple pulse mixing schemes on both channels has alleviated this problem.^{59–62}

The advantages of hetero-TOCSY become most apparent when long range correlation experiments are considered; for example, hetero-TOCSY has been shown to be extremely useful for ¹H detected ³¹P correlation spectroscopy of nucleic acids.^{63,64}

1 INTRODUCTION

Nuclear magnetic resonance is uniquely capable of revealing structure and dynamics on a molecular level. An understanding of nuclear spin relaxation is fundamental to an understanding of nuclear magnetic resonance in general. The theoretical framework needed to promote this understanding is conveniently constructed in terms of the time evolution of the density operator under the influence of some Hamiltonian as expressed by the Liouville–von Neuman equation. The emphasis here will be on molecules in liquids, though many of the principles presented are applicable to solids and gases. The experimental observables of NMR are oscillatory magnetizations induced in a sample as a consequence of subjecting it to various static and time-varying magnetic fields. The quantum mechanical operators corresponding to these observables act only on the nuclear spin degrees of freedom of the system. Furthermore, these operators are proportional to the spin angular momentum operators or products thereof, and, hence, can be dealt with using finite basis sets of states or operators. Relaxation, however, is a consequence of interactions between the nuclear spins and the rest of the system, referred to as the ‘lattice’. In most cases, the lattice cannot be treated exactly using quantum mechanics, because the density operator and the Hamiltonian cannot be defined exactly. The strategy generally employed, then, is to treat the effects of the lattice classically as a random time-dependent modulation of the nuclear spin operators while retaining a quantum mechanical description of the nuclear spins themselves. All externally applied magnetic fields are likewise treated classically. Our goal is to derive equations that correctly describe the observed temporal behavior of the experimental observables. This is done by proposing a Hamiltonian for the system under study, solving the Liouville–von Neuman equation for the time evolution of the density operator, computing the expected time evolution of the experimental observables, and comparing the result with measured values of these observables. Secondly, one wants to extract from this temporal behavior of the observables information about the fundamental nature of the system under investigation. For example, internuclear distances and rates of molecular reorientation due to Brownian motion can dramatically affect the

results of an NMR experiment. How can this kind of information be extracted from the behavior of the magnetization in a sample as a function of time? This article will lay out the theoretical framework of NMR experiments, with emphasis on an understanding of nuclear spin relaxation in liquids.

This article presumes a basic knowledge of the nuclear magnetic resonance phenomenon, including nuclear spin polarization in an external static magnetic field and interaction of nuclear spins with applied radiofrequency fields. For those not acquainted with these concepts, several basic texts may be consulted.^{1–3} The reader is assumed to have some grasp of basic quantum mechanics and angular momentum theory at the level generally taught in undergraduate physical chemistry courses. Some command of linear algebra and integral and differential calculus is also assumed. All abbreviations and symbols are either defined in the endpapers or are defined in context. Vectors and matrices will be distinguished by bold italic and bold roman type, respectively, and the same symbol in normal weight type will denote the magnitude of a vector or, with appropriate subscripts, components of a vector or elements of a matrix. Quantum mechanical operators will have a hat, for example, $\hat{H}$. Liouville space operators will have a double hat, for example $\hat{\hat{L}}$.

It is a familiar concept that the wavefunction embodies all that can be known about a quantum mechanical system and that any wavefunction can be expressed as a linear combination of the members of a complete set of eigenfunctions of the Hamiltonian of the system. However, in NMR, the density operator has proven to be a more convenient vehicle for this information, and the density operator, the Hamiltonian, and all other operators associated with the system can be cast as linear combinations of a complete set of orthonormal operators. These two descriptions are completely equivalent, and each can be formulated from the general concepts embodied in the bracket notation introduced by Dirac⁴ to describe abstract vector spaces. For nuclear spin systems in liquids, it is often possible to focus on a small number of spins (all the spins in one molecule, for example) and to consider the macroscopic sample as an ensemble of such systems, identical in their dependence on quantum mechanical operators but sampling the distribution of random classical variables. Since each nuclear spin has only a small number of eigenstates and the number of eigenstates for the whole system is the product of the numbers for each of the component spins, the necessary mathematics reduces, by means of an ensemble average, to a problem in linear algebra of reasonable dimension. In the following sections, the mathematics needed to discuss most of the experiments done on liquid samples will be formulated. Space limitations make it impossible to give a completely detailed exposition; for this, the reader may consult several excellent texts.^{5–9}

2 OPERATORS AND OPERATOR BASES

When a quantum mechanical system has a finite number of discrete energy levels (suppose there are n of them), the operators and states of the system can be represented as matrices and vectors in an n -dimensional vector space. Thus, the algebra of abstract n -dimensional vector spaces is essential to the theory we wish to develop. Dirac developed a convenient notation for describing these concepts.

2.1 Dirac Bracket Notation

For now, let us develop the bracket notation in a very abstract sense. It is important to realize that the bracket notation is just a formalism and can be applied to represent any desired vector space. Later, we shall apply it to both Hilbert and Liouville representations of the density operator. In the following equation is defined something called a *bra* and something called a *ket*:

$$\langle \text{bra} | (c) | \text{ket} \rangle \quad (1)$$

Bras and kets may have any kind of label inside to distinguish one from another. A ket may be converted into the corresponding bra by taking the Hermitian conjugate or adjoint, i.e., the complex conjugate transpose, and, of course, a bra can be converted into a ket in the same manner:

$$\langle \text{bra} | = [(| \text{ket} \rangle)^*]^T = (| \text{ket} \rangle)^\dagger \quad (2)$$

Multiplication of a bra and a ket in that order yields a number that can be real, imaginary, or complex:

$$\langle \text{bra} | \text{ket} \rangle = c \quad (3)$$

Note that this *scalar product* is not commutative, as we shall see in equation (9). Equation (3) is a key concept. In what follows, one must be able to recognize the $\langle | \rangle$ construct as a number that commutes with operators, bras, and kets. The scalar product is linear:

$$\left. \begin{aligned} \langle \text{bra} | (| \text{ket}_1 \rangle + | \text{ket}_2 \rangle) \rangle &= \langle \text{bra} | \text{ket}_1 \rangle + \langle \text{bra} | \text{ket}_2 \rangle \\ (\langle \text{bra}_1 | + \langle \text{bra}_2 |) | \text{ket} \rangle &= \langle \text{bra}_1 | \text{ket} \rangle + \langle \text{bra}_2 | \text{ket} \rangle \end{aligned} \right\} \quad (4)$$

Next we define something called an *operator* that converts a ket into some other ket:

$$\widehat{Op} | \text{ket} \rangle = | \text{new ket} \rangle \quad (5)$$

Operators will be distinguished by a hat (circumflex). Operators do not, in general, commute. The identity operator $\hat{E}$ just leaves a ket unaltered:

$$\hat{E} | \text{ket} \rangle = | \text{ket} \rangle \quad (6)$$

The identity operator does commute with all other operators.

Taking the adjoint of both sides of equation (5) yields the following relationship, which shows how an operator can act to the left on a bra:

$$(\widehat{Op} | \text{ket} \rangle)^\dagger = \langle \text{bra} | \widehat{Op}^\dagger = \langle \text{new bra} | \quad (7)$$

If $\widehat{Op}^\dagger = \widehat{Op}$, the operator is said to be *Hermitian* or *self-adjoint*.

If an operator acting on a ket yields the same ket multiplied by a number c (perhaps complex), the ket is said to be an *eigenket* of the operator, and c is the *eigenvalue*:

$$\widehat{Op} | \text{ket} \rangle = c | \text{ket} \rangle \quad (8)$$

As mentioned above, multiplication of bras and kets is not commutative, so the question arises of the meaning of the following product of a ket with a bra:

$$| \text{ket} \rangle \langle \text{bra} | = \text{operator} \quad (9)$$

This is called the *outer product* or *tensor product* of the bra and ket. Equation (9) asserts that this combination is an operator. This assertion can be easily proven by operating on some ket:

$$| a \rangle \langle b | c \rangle = | a \rangle \langle b | c \rangle = | a \rangle n_{bc} = n_{bc} | a \rangle \quad (10)$$

Remember that $\langle b | c \rangle$ is just a number, by equation (3), and a number will commute with a ket. Thus, $| a \rangle \langle b |$ satisfies the definition of an operator as in equation (5), because it produces a new ket $| a \rangle$ from $| c \rangle$. The numerical coefficient involved is not a problem, because a number times a ket is still a ket. The fact that one can reinterpret or regroup bras and kets in this way is a key concept of the formalism. In Section 2.2 it will become more obvious why these alternative interpretations are possible. We shall not put a hat over these operators, since there is no possibility of confusion; expressions of the type $| \rangle \langle |$ will always be interpretable as operators.

If we have a set of kets $\{ | i \rangle, i = 1, 2, 3, \dots, n \}$ such that

$$\langle i | j \rangle = \delta_{ij} \quad \text{for all } i, j = 1, 2, 3, \dots, n \quad (11)$$

then the set is said to be an *orthonormal* (orthogonal and normalized) basis. The Kronecker delta function is defined by

$$\delta_{ij} = \begin{cases} 1 & (i = j) \\ 0 & (i \neq j) \end{cases} \quad (12)$$

If for some member of the set $\langle i | i \rangle \neq 1$ then we simply define a new ket $| i' \rangle = | i \rangle / \langle i | i \rangle^{1/2}$ to replace $| i \rangle$ until all members of the set are normalized.

With just these simple rules for manipulating operators, bras, and kets as postulates, one can develop the mathematics necessary to treat nuclear spin dynamics.

2.2 Representations

Suppose we have some system in a state that corresponds to an abstract vector or ket designated as $| \psi(t) \rangle$. The indicated time dependence shows that the system may be evolving in time. We attempt to expand this state in the stationary orthonormal set of equation (11) as follows, and we want to know the form of the coefficients $c_i(t)$:

$$| \psi(t) \rangle = \sum_{i=1}^n c_i(t) | i \rangle \quad (13)$$

Multiplying from the left by $\langle i |$, a bra corresponding to one of the members of the basis set, and using equation (11) yields

$$\begin{aligned} \langle i | \psi(t) \rangle &= \langle i | \sum_{j=1}^n c_j(t) | j \rangle \\ &= \sum_{j=1}^n c_j(t) \langle i | j \rangle \\ &= \sum_{j=1}^n c_j(t) \delta_{ij} = c_i(t) \end{aligned} \quad (14)$$

The last step follows because, by equation (12), only the i th term survives in the sum. This is a formal prescription for computing the expansion coefficients; later, we shall see how it is implemented in real cases. The question of whether the set $\{|i\rangle\}$ is complete, i.e., contains all the basis vectors necessary to represent $|\psi(t)\rangle$, will not be addressed here. It will simply be asserted that such a set can be found. Taking the adjoint of both sides of equation (14) yields the analogous equation for bras:

$$\langle\psi(t)|i\rangle = c_i^*(t) \quad (15)$$

Having chosen a basis set, we can compute all the coefficients needed for equation (14) or equation (15). If these coefficients are arranged in a column or a row vector then we have the Hilbert space representation of the state (bra or ket) in the basis:

$$|\psi\rangle \xrightarrow{|i\rangle} \begin{bmatrix} \langle 1|\psi\rangle \\ \langle 2|\psi\rangle \\ \langle 3|\psi\rangle \\ \vdots \\ \langle n|\psi\rangle \end{bmatrix} = \begin{bmatrix} c_1 \\ c_2 \\ c_3 \\ \vdots \\ c_n \end{bmatrix} \quad (16a)$$

$$\begin{aligned} \langle\psi| \xrightarrow{|i\rangle} & [\langle\psi|1\rangle \quad \langle\psi|2\rangle \quad \langle\psi|3\rangle \quad \dots \quad \langle\psi|n\rangle] \\ & = [c_1^* \quad c_2^* \quad c_3^* \quad \dots \quad c_n^*] \end{aligned} \quad (16b)$$

A mapping of this sort is sometimes written with an equals sign in the literature. This is not consistent with the notation we have developed, because the state $|\psi\rangle$ is an abstraction implying no particular basis, whereas the vector representing $|\psi\rangle$ requires that a particular basis be chosen. It is also inconsistent to equate a wavefunction to a ket, because a wavefunction is a representation of the ket in a continuous rather than a discrete basis. The result is a function rather than a vector with discrete elements; that is why it is called a *wavefunction*. In this article, mappings of this sort will be indicated by an arrow as in equation (16). The basis used will be indicated as shown or will be obvious from the context.

Of course, the members of the basis set can themselves be represented in the basis. If the j th member of the basis is represented then all the elements of the vector will be zero except the j th, which is one:

$$|j\rangle \xrightarrow{|i\rangle} \begin{bmatrix} \langle 1|j\rangle \\ \langle 2|j\rangle \\ \vdots \\ \langle j|j\rangle \\ \vdots \\ \langle n|j\rangle \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 1 \\ \vdots \\ 0 \end{bmatrix} \quad (17a)$$

$$\begin{aligned} \langle j| \xrightarrow{|i\rangle} & [\langle j|1\rangle \quad \langle j|2\rangle \quad \dots \quad \langle j|j\rangle \quad \dots \quad \langle j|n\rangle] \\ & = [0 \quad 0 \quad \dots \quad 1 \quad \dots \quad 0] \end{aligned} \quad (17b)$$

If we rewrite equation (13) using the result in equation (14) and commute the number with the ket on the right, we have

$$\begin{aligned} |\psi(t)\rangle &= \sum_{i=1}^n \langle i|\psi(t)\rangle |i\rangle \\ &= \sum_{i=1}^n |i\rangle \langle i|\psi(t)\rangle \\ &= \left(\sum_{i=1}^n |i\rangle \langle i| \right) |\psi(t)\rangle \end{aligned} \quad (18)$$

Written this way, the implication is

$$\sum_{i=1}^n |i\rangle \langle i| = \hat{E} \quad (19)$$

Rearranging and reinterpreting the brackets in this way may seem quite strange at first, but the examples given below should clarify the formalism. The operators $|i\rangle \langle i|$ are called *projection operators* because they project from any state the part that projects on the i th basis state. Summing over all the projection operators then just gives the unit operator.

Suppose we have two alternative sets of basis states, $\{|a,i\rangle\}$ and $\{|b,i\rangle\}$, spanning the same vector space; then we can effect a transformation between the bases using projection operators as in equation (19). Projecting the b basis onto the a basis, we have

$$\begin{aligned} |b,i\rangle &= \left(\sum_{j=1}^n |a,j\rangle \langle a,j| \right) |b,i\rangle \\ &= \sum_{j=1}^n |a,j\rangle \langle a,j|b,i\rangle \\ &= \sum_{j=1}^n \langle a,j|b,i\rangle |a,j\rangle \end{aligned} \quad (20)$$

If we have an arbitrary state represented in the b basis, it can be transformed to the a basis as follows:

$$\begin{aligned} \psi &= \sum_{i=1}^n \langle b,i|\psi\rangle |b,i\rangle \\ &= \sum_{i=1}^n \langle b,i|\psi\rangle \sum_{j=1}^n \langle a,j|b,i\rangle |a,j\rangle \\ &= \sum_{i,j=1}^n \langle a,j|b,i\rangle \langle b,i|\psi\rangle |a,j\rangle \end{aligned} \quad (21a)$$

$$\begin{aligned} \langle\psi| &= \sum_{i=1}^n \langle\psi|b,i\rangle \langle b,i| \\ &= \sum_{i=1}^n \langle\psi|b,i\rangle \sum_{j=1}^n \langle b,i|a,j\rangle \langle a,j| \\ &= \sum_{i,j=1}^n \langle\psi|b,i\rangle \langle b,i|a,j\rangle \langle a,j| \end{aligned} \quad (21b)$$

4 LIOUVILLE EQUATION OF MOTION

Comparing these results with equations (16a) and (16b), it is apparent that equations (21a) and (21b) can be represented as follows:

$$\begin{aligned} & \begin{bmatrix} \langle a, 1|\psi \rangle \\ \langle a, 2|\psi \rangle \\ \langle a, 3|\psi \rangle \\ \vdots \\ \langle a, n|\psi \rangle \end{bmatrix} \\ &= \begin{bmatrix} \langle a, 1|b, 1 \rangle & \langle a, 1|b, 2 \rangle & \langle a, 1|b, 3 \rangle & \dots & \langle a, 1|b, n \rangle \\ \langle a, 2|b, 1 \rangle & \langle a, 2|b, 2 \rangle & \langle a, 2|b, 3 \rangle & \dots & \langle a, 2|b, n \rangle \\ \langle a, 3|b, 1 \rangle & \langle a, 3|b, 2 \rangle & \langle a, 3|b, 3 \rangle & \dots & \langle a, 3|b, n \rangle \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \langle a, n|b, 1 \rangle & \langle a, n|b, 2 \rangle & \langle a, n|b, 3 \rangle & \dots & \langle a, n|b, n \rangle \end{bmatrix} \\ &\quad \times \begin{bmatrix} \langle b, 1|\psi \rangle \\ \langle b, 2|\psi \rangle \\ \langle b, 3|\psi \rangle \\ \vdots \\ \langle b, n|\psi \rangle \end{bmatrix} \end{aligned} \quad (22a)$$

$$\begin{aligned} & [\langle \psi|a, 1 \rangle \quad \langle \psi|a, 2 \rangle \quad \langle \psi|a, 3 \rangle \quad \dots \quad \langle \psi|a, n \rangle] \\ &= [\langle \psi|b, 1 \rangle \quad \langle \psi|b, 2 \rangle \quad \langle \psi|b, 3 \rangle \quad \dots \quad \langle \psi|b, n \rangle] \\ &\quad \times \begin{bmatrix} \langle b, 1|a, 1 \rangle & \langle b, 1|a, 2 \rangle & \langle b, 1|a, 3 \rangle & \dots & \langle b, 1|a, n \rangle \\ \langle b, 2|a, 1 \rangle & \langle b, 2|a, 2 \rangle & \langle b, 2|a, 3 \rangle & \dots & \langle b, 2|a, n \rangle \\ \langle b, 3|a, 1 \rangle & \langle b, 3|a, 2 \rangle & \langle b, 3|a, 3 \rangle & \dots & \langle b, 3|a, n \rangle \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \langle b, n|a, 1 \rangle & \langle b, n|a, 2 \rangle & \langle b, n|a, 3 \rangle & \dots & \langle b, n|a, n \rangle \end{bmatrix} \end{aligned} \quad (22b)$$

Note that the columns of the first transformation matrix are merely the representation of the b basis kets in the a basis, while the rows are the representation of the a bras in the b basis. The second transformation matrix is the adjoint (complex conjugate transpose) of the first. If the two matrices are multiplied in either order, the result is a unit matrix, because the basis states are normalized. But this is just the definition of a unitary matrix. In compact matrix notation, we have

$$\psi_a = \mathbf{T}\psi_b, \quad \psi_a^\dagger = \psi_b^\dagger \mathbf{T}^\dagger \quad (23)$$

The unitary nature of the transformation is expressed as

$$\mathbf{T}\mathbf{T}^\dagger = \mathbf{T}^\dagger \mathbf{T} = \mathbf{E} = \mathbf{T}\mathbf{T}^{-1} = \mathbf{T}^{-1}\mathbf{T} \quad (24)$$

From these two equations, it is evident that the normalization of the state is preserved, regardless of the representation used:

$$\psi_a^\dagger \psi_a = \psi_b^\dagger \mathbf{T}^\dagger \mathbf{T} \psi_b = \psi_b^\dagger \psi_b \quad (25)$$

The inverse transformation can easily be derived. If $\psi_a = \mathbf{T}\psi_b$ then we have

$$\mathbf{T}^{-1}\mathbf{T}\psi_b = \mathbf{T}^{-1}\psi_a, \quad \psi_b = \mathbf{T}^{-1}\psi_a \quad (26)$$

But the inverse transformation is

$$\begin{aligned} |\psi\rangle &= \sum_{i=1}^n \langle a, i|\psi\rangle |a, i\rangle \\ &= \sum_{i=1}^n \langle a, i|\psi\rangle \sum_{j=1}^n \langle b, j|a, i\rangle |b, j\rangle \\ &= \sum_{i,j=1}^n \langle b, j|a, i\rangle \langle a, i|\psi\rangle |b, j\rangle \end{aligned} \quad (27)$$

Comparing equations (21a) and (27), the relationship between the a to b and b to a transforms is found to be

$$T_{ji}^* = \langle b, i|a, j\rangle^* = \langle a, j|b, i\rangle = T_{ij}^\dagger \quad (28)$$

which shows that the inverse transformation matrix $\mathbf{T}^{-1}$ is just the adjoint of the original matrix—but this is again just the definition of a unitary matrix. Examining equations (22a) and (22b), it is clear that the complex conjugate transpose of the transformation matrix is, indeed, the desired inverse transformation. This may be shown more easily by noting from equation (24) that $\mathbf{T}^\dagger = \mathbf{T}^{-1}$. Then, from equation (23), we have

$$\left. \begin{aligned} \mathbf{T}^\dagger \psi_a &= \mathbf{T}^\dagger \mathbf{T} \psi_b = \psi_b \\ \psi_a^\dagger \mathbf{T} &= \psi_b^\dagger \mathbf{T}^\dagger \mathbf{T} = \psi_b^\dagger \end{aligned} \right\} \quad (29)$$

We now turn to some relationships involving operators. Suppose one has some arbitrary operator $\hat{O}$. Using equation (19), we can write

$$\begin{aligned} \hat{O} &= \left(\sum_{i=1}^n |i\rangle \langle i| \right) \hat{O} \left(\sum_{j=1}^n |j\rangle \langle j| \right) \\ &= \sum_{i,j=1}^n |i\rangle \langle i| \hat{O} |j\rangle \langle j| \\ &= \sum_{i,j=1}^n \langle i| \hat{O} |j\rangle |i\rangle \langle j| \\ &= \sum_{i,j=1}^n c_{ij} |i\rangle \langle j| \end{aligned} \quad (30)$$

A unit operator can be inserted anywhere without affecting the equality. This equation is a prescription for writing any operator as a sum of operators $|i\rangle \langle j|$. Clearly, if there are n basis states $|i\rangle$ then there are n^2 basis operators $|i\rangle \langle j|$. If we multiply this equation from the left and right by a basis state, the result is a prescription for the coefficients c_{ij} :

$$\begin{aligned} \langle k| \hat{O} |l\rangle &= \langle k| \left(\sum_{i,j=1}^n c_{ij} |i\rangle \langle j| \right) |l\rangle \\ &= \sum_{i,j=1}^n c_{ij} \langle k|i\rangle \langle j|l\rangle \\ &= \sum_{i,j=1}^n c_{ij} \delta_{ki} \delta_{jl} = c_{kl} \end{aligned} \quad (31)$$

These coefficients are commonly called the *matrix elements* of the operator, and can be arranged in a matrix to form a Hilbert space representation of the operator:

$$\hat{O} \xrightarrow{|i\rangle} \mathbf{O} = \begin{bmatrix} \langle 1|\hat{O}|1\rangle & \langle 1|\hat{O}|2\rangle & \langle 1|\hat{O}|3\rangle & \dots & \langle 1|\hat{O}|n\rangle \\ \langle 2|\hat{O}|1\rangle & \langle 2|\hat{O}|2\rangle & \langle 2|\hat{O}|3\rangle & \dots & \langle 2|\hat{O}|n\rangle \\ \langle 3|\hat{O}|1\rangle & \langle 3|\hat{O}|2\rangle & \langle 3|\hat{O}|3\rangle & \dots & \langle 3|\hat{O}|n\rangle \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \langle n|\hat{O}|1\rangle & \langle n|\hat{O}|2\rangle & \langle n|\hat{O}|3\rangle & \dots & \langle n|\hat{O}|n\rangle \end{bmatrix} \quad (32)$$

Proceeding as in equation (25), we can write

$$\psi_a^\dagger \mathbf{O}_a \psi_a = \psi_b^\dagger \mathbf{T}^\dagger \mathbf{T} \mathbf{O}_a \mathbf{T}^\dagger \psi_b = \psi_b^\dagger \mathbf{O}_b \psi_b \quad (33)$$

where we have defined the operator in the b basis as

$$\mathbf{O}_b = \mathbf{T} \mathbf{O}_a \mathbf{T}^\dagger \quad (34)$$

Analogously, the basis operators themselves can be represented as follows to yield a matrix of all zero elements except the ij th:

$$\begin{aligned} |i\rangle\langle j| \xrightarrow{|i\rangle} & \begin{bmatrix} \langle 1|i\rangle\langle j|1\rangle & \langle 1|i\rangle\langle j|2\rangle & \dots & \langle 1|i\rangle\langle j|j\rangle & \dots & \langle 1|i\rangle\langle j|n\rangle \\ \langle 2|i\rangle\langle j|1\rangle & \langle 2|i\rangle\langle j|2\rangle & \dots & \langle 2|i\rangle\langle j|j\rangle & \dots & \langle 2|i\rangle\langle j|n\rangle \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ \langle i|i\rangle\langle j|1\rangle & \langle i|i\rangle\langle j|2\rangle & \dots & \langle i|i\rangle\langle j|j\rangle & \dots & \langle i|i\rangle\langle j|n\rangle \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ \langle n|i\rangle\langle j|1\rangle & \langle n|i\rangle\langle j|2\rangle & \dots & \langle n|i\rangle\langle j|j\rangle & \dots & \langle n|i\rangle\langle j|n\rangle \end{bmatrix} \\ &= \begin{bmatrix} 0 & 0 & \dots & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 1 & \dots & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 0 & \dots & 0 \end{bmatrix} \end{aligned} \quad (35)$$

This result can also be obtained from equations (17a) and (17b) by writing

$$\begin{aligned} & \begin{bmatrix} \langle 1|i\rangle \\ \langle 2|i\rangle \\ \vdots \\ \langle j|i\rangle \\ \vdots \\ \langle n|i\rangle \end{bmatrix} [\langle j|1\rangle \quad \langle j|2\rangle \quad \dots \quad \langle j|j\rangle \quad \dots \quad \langle j|n\rangle] \\ &= \begin{bmatrix} \langle 1|i\rangle\langle j|1\rangle & \langle 1|i\rangle\langle j|2\rangle & \dots & \langle 1|i\rangle\langle j|j\rangle & \dots & \langle 1|i\rangle\langle j|n\rangle \\ \langle 2|i\rangle\langle j|1\rangle & \langle 2|i\rangle\langle j|2\rangle & \dots & \langle 2|i\rangle\langle j|j\rangle & \dots & \langle 2|i\rangle\langle j|n\rangle \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ \langle i|i\rangle\langle j|1\rangle & \langle i|i\rangle\langle j|2\rangle & \dots & \langle i|i\rangle\langle j|j\rangle & \dots & \langle i|i\rangle\langle j|n\rangle \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ \langle n|i\rangle\langle j|1\rangle & \langle n|i\rangle\langle j|2\rangle & \dots & \langle n|i\rangle\langle j|j\rangle & \dots & \langle n|i\rangle\langle j|n\rangle \end{bmatrix} \end{aligned} \quad (36)$$

The basis operators are orthogonal, just as the basis states are; however, the inner product exemplified by equation (11) must

be replaced by the trace operation:

$$\begin{aligned} \text{Tr}(|j\rangle\langle k|l\rangle\langle m|) &= \sum_{i=1}^n \langle i|j\rangle\langle k|l\rangle\langle m|i\rangle \\ &= \langle k|l\rangle\langle m|j\rangle \\ &= \delta_{kl}\delta_{mj} \end{aligned} \quad (37)$$

In equation (37), the right-hand side will be nonzero if and only if $j = m$ and $k = l$; then

$$|j\rangle\langle k|k\rangle\langle j| = |j\rangle\langle k|(|j\rangle\langle k|)^\dagger \quad (38)$$

In order to simplify notation, we now make a mapping of the indices j and k of $|j\rangle\langle k|$ onto a single index i of $\hat{U}_i$. This is simply a relabeling of the basis operators. The exact nature of the mapping is arbitrary, except that there must be a one-to-one correspondence between the pair of indices j, k and the index i . The expression corresponding to equation (37) is then

$$\text{Tr}(\hat{U}_i \hat{U}_j^\dagger) = \delta_{ij} \quad (39)$$

This equation is the normalization condition for basis operators analogous to equation (11). Note that if the basis states used in equation (37) are normalized then these basis operators will also be normalized.

If we expand the generic operator $\hat{O}$ in terms of this basis set, the result is

$$\hat{O} = \sum_{i=1}^{n^2} c_i \hat{U}_i \quad (40)$$

Now, if this equation is multiplied by $\hat{U}_j^\dagger$ and the trace taken, a prescription is obtained for the expansion coefficients c_i :

$$\begin{aligned} \text{Tr}(\hat{O} \hat{U}_j^\dagger) &= \text{Tr}\left(\sum_{i=1}^{n^2} c_i \hat{U}_i \hat{U}_j^\dagger\right) \\ &= \sum_{i=1}^{n^2} c_i \text{Tr}(\hat{U}_i \hat{U}_j^\dagger) = \sum_{i=1}^{n^2} c_i \delta_{ij} = c_j \end{aligned} \quad (41)$$

Equation (40) may then be rewritten as

$$\hat{O} = \sum_{i=1}^{n^2} \text{Tr}(\hat{O} \hat{U}_i^\dagger) \hat{U}_i \quad (42)$$

The coefficients in this equation can be arranged in a vector to form the Liouville space representation of the operator:

$$\hat{O} \xrightarrow{\hat{U}_i} \begin{bmatrix} \text{Tr}(\hat{O} \hat{U}_1^\dagger) \\ \text{Tr}(\hat{O} \hat{U}_2^\dagger) \\ \text{Tr}(\hat{O} \hat{U}_3^\dagger) \\ \vdots \\ \text{Tr}(\hat{O} \hat{U}_{n^2}^\dagger) \end{bmatrix} \quad (43)$$

Note that this space is n^2 -dimensional.

As was done with basis states, it is possible to transform among alternative sets of basis operators. Consider a new operator basis $\{\hat{V}_i, i = 1, 2, 3, \dots, n^2\}$. These operators can be expressed in the original basis as

$$\hat{V}_i = \sum_{j=1}^{n^2} \text{Tr}(\hat{V}_i \hat{U}_j^\dagger) \hat{U}_j \quad (44)$$

Equation (42) can be written in terms of the $\hat{V}_i$; then equation (44) can be substituted:

$$\begin{aligned} \hat{O} &= \sum_{j=1}^{n^2} \text{Tr}(\hat{O} \hat{V}_j^\dagger) \hat{V}_j \\ &= \sum_{j=1}^{n^2} \text{Tr}(\hat{O} \hat{V}_j^\dagger) \sum_{i=1}^{n^2} \text{Tr}(\hat{V}_j \hat{U}_i^\dagger) \hat{U}_i \\ &= \sum_{i,j=1}^{n^2} \text{Tr}(\hat{V}_j \hat{U}_i^\dagger) \text{Tr}(\hat{O} \hat{V}_j^\dagger) \hat{U}_i \end{aligned} \quad (45)$$

Comparing equations (42) and (45), it is evident that the conversion of operator bases is accomplished as follows:

$$\text{Tr}(\hat{O} \hat{U}_i^\dagger) = \sum_{j=1}^{n^2} \text{Tr}(\hat{V}_j \hat{U}_i^\dagger) \text{Tr}(\hat{O} \hat{V}_j^\dagger) \quad (46)$$

In terms of the Liouville space representation, this can be written as

$$\begin{aligned} &\begin{bmatrix} \text{Tr}(\hat{O} \hat{U}_1^\dagger) \\ \text{Tr}(\hat{O} \hat{U}_2^\dagger) \\ \text{Tr}(\hat{O} \hat{U}_3^\dagger) \\ \vdots \\ \text{Tr}(\hat{O} \hat{U}_{n^2}^\dagger) \end{bmatrix} \\ &= \begin{bmatrix} \text{Tr}(\hat{V}_1 \hat{U}_1^\dagger) & \text{Tr}(\hat{V}_2 \hat{U}_1^\dagger) & \text{Tr}(\hat{V}_3 \hat{U}_1^\dagger) & \dots & \text{Tr}(\hat{V}_{n^2} \hat{U}_1^\dagger) \\ \text{Tr}(\hat{V}_1 \hat{U}_2^\dagger) & \text{Tr}(\hat{V}_2 \hat{U}_2^\dagger) & \text{Tr}(\hat{V}_3 \hat{U}_2^\dagger) & \dots & \text{Tr}(\hat{V}_{n^2} \hat{U}_2^\dagger) \\ \text{Tr}(\hat{V}_1 \hat{U}_3^\dagger) & \text{Tr}(\hat{V}_2 \hat{U}_3^\dagger) & \text{Tr}(\hat{V}_3 \hat{U}_3^\dagger) & \dots & \text{Tr}(\hat{V}_{n^2} \hat{U}_3^\dagger) \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \text{Tr}(\hat{V}_1 \hat{U}_{n^2}^\dagger) & \text{Tr}(\hat{V}_2 \hat{U}_{n^2}^\dagger) & \text{Tr}(\hat{V}_3 \hat{U}_{n^2}^\dagger) & \dots & \text{Tr}(\hat{V}_{n^2} \hat{U}_{n^2}^\dagger) \end{bmatrix} \\ &\quad \times \begin{bmatrix} \text{Tr}(\hat{O} \hat{V}_1^\dagger) \\ \text{Tr}(\hat{O} \hat{V}_2^\dagger) \\ \text{Tr}(\hat{O} \hat{V}_3^\dagger) \\ \vdots \\ \text{Tr}(\hat{O} \hat{V}_{n^2}^\dagger) \end{bmatrix} \end{aligned} \quad (47)$$

2.3 Direct Product Bases

It is quite common that one is able to derive a basis for two or more parts of a system using the techniques described in the previous section, but it is then desired to represent the whole

system so that interactions among the parts can be considered. For example, a molecule might contain two spins, say a ^{13}C nucleus and a ^1H nucleus. For this purpose, we introduce the *direct* or *outer product* of the subspaces to form the space appropriate for the whole system. One can form the direct products in either Hilbert space or Liouville space. The only new definitions needed are as follows. For vectors (states),

$$|\psi_1\rangle|\psi_2\rangle = |\psi\rangle \quad (48a)$$

$$\begin{bmatrix} \langle 1, 1|\psi_1\rangle \\ \langle 1, 2|\psi_1\rangle \\ \langle 1, 3|\psi_1\rangle \\ \vdots \\ \langle 1, n|\psi_1\rangle \end{bmatrix} \otimes \begin{bmatrix} \langle 2, 1|\psi_2\rangle \\ \langle 2, 2|\psi_2\rangle \\ \langle 2, 3|\psi_2\rangle \\ \vdots \\ \langle 2, m|\psi_2\rangle \end{bmatrix} = \begin{bmatrix} \langle 1, 1|\psi_1\rangle \begin{bmatrix} \langle 2, 1|\psi_2\rangle \\ \langle 2, 2|\psi_2\rangle \\ \langle 2, 3|\psi_2\rangle \\ \vdots \\ \langle 2, m|\psi_2\rangle \end{bmatrix} \\ \langle 1, 2|\psi_1\rangle \begin{bmatrix} \langle 2, 1|\psi_2\rangle \\ \langle 2, 2|\psi_2\rangle \\ \langle 2, 3|\psi_2\rangle \\ \vdots \\ \langle 2, m|\psi_2\rangle \end{bmatrix} \\ \langle 1, 3|\psi_1\rangle \begin{bmatrix} \langle 2, 1|\psi_2\rangle \\ \langle 2, 2|\psi_2\rangle \\ \langle 2, 3|\psi_2\rangle \\ \vdots \\ \langle 2, m|\psi_2\rangle \end{bmatrix} \\ \vdots \\ \langle 1, n|\psi_1\rangle \begin{bmatrix} \langle 2, 1|\psi_2\rangle \\ \langle 2, 2|\psi_2\rangle \\ \langle 2, 3|\psi_2\rangle \\ \vdots \\ \langle 2, m|\psi_2\rangle \end{bmatrix} \end{bmatrix} \quad (48b)$$

A slightly more condensed notation is required to make the corresponding definition for matrices (operators) manageable:

$$\hat{O} = \hat{O}^{(1)} \otimes \hat{O}^{(2)} \quad (49a)$$

$$\mathbf{O} = \begin{bmatrix} O_{1,1}^{(1)} \mathbf{O}^{(2)} & O_{1,2}^{(1)} \mathbf{O}^{(2)} & O_{1,3}^{(1)} \mathbf{O}^{(2)} & \dots & O_{1,n}^{(1)} \mathbf{O}^{(2)} \\ O_{2,1}^{(1)} \mathbf{O}^{(2)} & O_{2,2}^{(1)} \mathbf{O}^{(2)} & O_{2,3}^{(1)} \mathbf{O}^{(2)} & \dots & O_{2,n}^{(1)} \mathbf{O}^{(2)} \\ O_{3,1}^{(1)} \mathbf{O}^{(2)} & O_{3,2}^{(1)} \mathbf{O}^{(2)} & O_{3,3}^{(1)} \mathbf{O}^{(2)} & \dots & O_{3,n}^{(1)} \mathbf{O}^{(2)} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ O_{n,1}^{(1)} \mathbf{O}^{(2)} & O_{n,2}^{(1)} \mathbf{O}^{(2)} & O_{n,3}^{(1)} \mathbf{O}^{(2)} & \dots & O_{n,n}^{(1)} \mathbf{O}^{(2)} \end{bmatrix} \quad (49b)$$

$$\mathbf{O}^{(2)} = \begin{bmatrix} O_{1,1}^{(2)} & O_{1,2}^{(2)} & O_{1,3}^{(2)} & \dots & O_{1,m}^{(2)} \\ O_{2,1}^{(2)} & O_{2,2}^{(2)} & O_{2,3}^{(2)} & \dots & O_{2,m}^{(2)} \\ O_{3,1}^{(2)} & O_{3,2}^{(2)} & O_{3,3}^{(2)} & \dots & O_{3,m}^{(2)} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ O_{m,1}^{(2)} & O_{m,2}^{(2)} & O_{m,3}^{(2)} & \dots & O_{m,m}^{(2)} \end{bmatrix} \quad (49c)$$

Note that the dimension of the product space is always the product of the dimensions of the subspaces.

In equation (43) the Liouville space was introduced. With the introduction of the concept of direct products, it is possible to give a more satisfying explanation of the mapping from Hilbert space to Liouville space. The Hilbert space operators $|i\rangle\langle j|$ can be mapped onto a Liouville space with the following basis states:

$$|i\rangle\langle j| = |ij\rangle \quad (50)$$

Clearly, a one-to-one mapping is possible. In Section 5, the use of Liouville space representations will be explored further with the introduction of superoperators.

It is common in the NMR literature to have implied direct products. For example, one might write $\hat{I}_z^{(1)} + \hat{I}_z^{(2)}$, where (1) and (2) refer to different spins. This is meant to imply $\hat{I}_z^{(1)} \otimes \hat{E}^{(2)} + \hat{E}^{(1)} \otimes \hat{I}_z^{(2)}$. Alternatively, one might encounter $\hat{I}_z \hat{I}_+$, where no direct product is implied, or $\hat{I}_+^{(1)} \hat{I}_-^{(2)}$, where we are to understand that this means $\hat{I}_+^{(1)} \otimes \hat{I}_-^{(2)}$. It is necessary to understand from the context and notation what is really meant.

3 SOME COMMONLY USED BASES

Next let us consider some examples of bases commonly used in NMR, using simple spin systems to illustrate how this formalism can be applied to nuclear spins.

3.1 The Single Spin Eigenstate Basis

A single isolated spin- $\frac{1}{2}$ nucleus has two energy eigenstates. They are commonly represented as $|\alpha\rangle$ and $|\beta\rangle$; however, since this notation is applicable only for spin- $\frac{1}{2}$, we shall also use the notation $|\frac{1}{2}\rangle$ and $|\frac{1}{2}\rangle$, respectively, where each state is labelled by its $\hat{I}_z$ eigenvalue (this will be discussed in more detail below). It is assumed that these states are orthonormal. Using equation (17a), we can write the Hilbert space representation of the basis states as

$$\left. \begin{aligned} |\alpha\rangle = |\frac{1}{2}\rangle &\rightarrow \begin{bmatrix} \langle\alpha|\alpha\rangle \\ \langle\beta|\alpha\rangle \end{bmatrix} = \begin{bmatrix} 1 \\ 0 \end{bmatrix} \\ |\beta\rangle = |-\frac{1}{2}\rangle &\rightarrow \begin{bmatrix} \langle\alpha|\beta\rangle \\ \langle\beta|\beta\rangle \end{bmatrix} = \begin{bmatrix} 0 \\ 1 \end{bmatrix} \end{aligned} \right\} \quad (51)$$

The corresponding Hilbert space representation of the basis operators can be obtained most easily using equation (36) to write

$$\left. \begin{aligned} \hat{U}_1 = |\alpha\rangle\langle\alpha| &\rightarrow \begin{bmatrix} 1 \\ 0 \end{bmatrix} \begin{bmatrix} 1 & 0 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \\ \hat{U}_2 = |\alpha\rangle\langle\beta| &\rightarrow \begin{bmatrix} 1 \\ 0 \end{bmatrix} \begin{bmatrix} 0 & 1 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix} \\ \hat{U}_3 = |\beta\rangle\langle\alpha| &\rightarrow \begin{bmatrix} 0 \\ 1 \end{bmatrix} \begin{bmatrix} 1 & 0 \end{bmatrix} = \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix} \\ \hat{U}_4 = |\beta\rangle\langle\beta| &\rightarrow \begin{bmatrix} 0 \\ 1 \end{bmatrix} \begin{bmatrix} 0 & 1 \end{bmatrix} = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix} \end{aligned} \right\} \quad (52)$$

It is easily verified that these matrices satisfy the orthonormality conditions by comparing with equation (39) for all pairs.

For spins with a higher angular momentum quantum number, the bases are similar but with higher dimension. For example, a spin-1 nucleus, like ^2H , has three eigenstates

and nine basis operators. Representations of basis states and operators for any nucleus can be obtained just as above knowing only the number of eigenstates and assuming that they are orthonormal.

3.2 The Basis Derived from Direct Products of Single Spin Bases

When the system of interest includes more than one spin, a direct product of single spin bases described in the previous section (one set corresponding to the correct spin for each nucleus) yields a basis for the combined system. The first state and the first operator for two spin- $\frac{1}{2}$ nuclei, for example, would be

$$\left. \begin{aligned} |\alpha\rangle \otimes |\alpha\rangle = |\alpha\alpha\rangle &\rightarrow \begin{bmatrix} 1 \\ 0 \end{bmatrix} \otimes \begin{bmatrix} 1 \\ 0 \end{bmatrix} \\ &= \begin{bmatrix} 1 & \begin{bmatrix} 1 \\ 0 \end{bmatrix} \\ 0 & \begin{bmatrix} 1 \\ 0 \end{bmatrix} \end{bmatrix} = \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \end{bmatrix} \\ \hat{U}_1 \otimes \hat{U}_1 &\rightarrow \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \otimes \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} = \begin{bmatrix} 1 & \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \\ 0 & \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \end{bmatrix} \\ &= \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \end{aligned} \right\} \quad (53)$$

The other 3 basis states and 15 operators are composed in the same fashion using all the pairs of single spin matrices.

3.3 The Basis Derived from the Eigenstates of the Hamiltonian

The states given in equation (51) for a single spin $\frac{1}{2}$ are the eigenstates of the Hamiltonian, but for two identical spin- $\frac{1}{2}$ nuclei (an A_2 spin system), the eigenstates are

$$\left. \begin{aligned} |A_2, 1\rangle = |\alpha\alpha\rangle &\rightarrow \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \end{bmatrix} \\ |A_2, 2\rangle = \sqrt{\frac{1}{2}}(|\alpha\beta\rangle + |\beta\alpha\rangle) &\rightarrow \begin{bmatrix} 0 \\ \sqrt{\frac{1}{2}} \\ \sqrt{\frac{1}{2}} \\ 0 \end{bmatrix} \\ |A_2, 3\rangle = \sqrt{\frac{1}{2}}(|\alpha\beta\rangle - |\beta\alpha\rangle) &\rightarrow \begin{bmatrix} 0 \\ \sqrt{\frac{1}{2}} \\ -\sqrt{\frac{1}{2}} \\ 0 \end{bmatrix} \\ |A_2, 4\rangle = |\beta\beta\rangle &\rightarrow \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \end{bmatrix} \end{aligned} \right\} \quad (54)$$

These equations show a representation of the eigenstates in the basis of the spin product states. Assembling these vectors into a unitary matrix according to equation (22a) gives the following transformation matrix from the spin product basis to the eigenbasis:

$$\mathbf{U} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \sqrt{\frac{1}{2}} & \sqrt{\frac{1}{2}} & 0 \\ 0 & \sqrt{\frac{1}{2}} & -\sqrt{\frac{1}{2}} & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (55)$$

It is easily verified that $\mathbf{U}\mathbf{U}^\dagger = \mathbf{U}\mathbf{U}^{-1} = \mathbf{E}$. Applying this transformation to the spin product states or operators yields the desired eigenstate basis for the Hilbert space representation or the Liouville space representation, respectively.

3.4 The Angular Momentum Operator Basis

For a single spin- $\frac{1}{2}$ nucleus, the components of the angular momentum vector operator $\hat{\mathbf{I}} = \{\hat{I}_x, \hat{I}_y, \hat{I}_z\}$ augmented by the identity operator $\hat{E}$ are a complete basis. For a development of the angular momentum operators from first principles, the reader is referred to the standard texts.^{6,7,10} We shall be content to define them according to their effect on the basis states as in equation (5). For any spin- I nucleus there are $2I + 1$ quantum states $|m\rangle$ such that

$$\left. \begin{aligned} \hat{I}_x|m\rangle &= \frac{1}{2} \{ [I(I+1) - m(m+1)]^{1/2} |m+1\rangle \\ &\quad + [I(I+1) - m(m-1)]^{1/2} |m-1\rangle \} \\ \hat{I}_y|m\rangle &= \frac{1}{2i} \{ [I(I+1) - m(m+1)]^{1/2} |m+1\rangle \\ &\quad - [I(I+1) - m(m-1)]^{1/2} |m-1\rangle \} \\ \hat{I}_z|m\rangle &= m|m\rangle \end{aligned} \right\} \quad (56)$$

The eigenvalue m ranges in integer steps such that $-I \leq m \leq I$. For spin- $\frac{1}{2}$, using the $\{|\frac{1}{2}\rangle, |-\frac{1}{2}\rangle\}$ basis, the angular momentum operators and their representations are

$$\begin{aligned} \hat{I}_x &\rightarrow \frac{1}{2} \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, & \hat{I}_y &\rightarrow \frac{1}{2i} \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix} \\ \hat{I}_z &\rightarrow \frac{1}{2} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}, & \hat{E} &\rightarrow \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \end{aligned} \quad (57)$$

It is easily verified that these operators are orthogonal but not normalized using equation (39). Normalization can easily be achieved by multiplying by the appropriate constants to satisfy equation (39); this yields the desired basis for spin- $\frac{1}{2}$:

$$\left. \begin{aligned} \hat{U}_1 &= \frac{1}{\sqrt{2}} \hat{E} \rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \\ \hat{U}_2 &= \sqrt{2} \hat{I}_z \rightarrow \frac{\sqrt{2}}{2} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \\ \hat{U}_3 &= \sqrt{2} \hat{I}_x \rightarrow \frac{\sqrt{2}}{2} \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \\ \hat{U}_4 &= \sqrt{2} \hat{I}_y \rightarrow \frac{\sqrt{2}}{2i} \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix} \end{aligned} \right\} \quad (58)$$

For a spin-1 nucleus, using equation (56), the angular momentum operators are

$$\left. \begin{aligned} \hat{I}_x &\rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix}, & \hat{I}_y &\rightarrow \frac{1}{i\sqrt{2}} \begin{bmatrix} 0 & 1 & 0 \\ -1 & 0 & 1 \\ 0 & -1 & 0 \end{bmatrix} \\ \hat{I}_z &\rightarrow \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{bmatrix} \end{aligned} \right\} \quad (59)$$

However, since nine basis operators are required for spin 1, augmenting this set with $\hat{E}$ would clearly not be sufficient to produce a complete basis. However, we shall defer enumerating the other members of this basis until the next section, because the task becomes much easier once the spherical tensor operators have been introduced.

3.5 The Spherical Tensor Operator Basis

Examination of equation (56) rapidly leads one to conclude that a simpler basis might be composed including the following operators:

$$\left. \begin{aligned} \hat{I}_+|m\rangle &= [I(I+1) - m(m+1)]^{1/2} |m+1\rangle \\ \hat{I}_-|m\rangle &= [I(I+1) - m(m-1)]^{1/2} |m-1\rangle \end{aligned} \right\} \quad (60)$$

These operators are commonly called the *raising* or *step-up* and *lowering* or *step-down* operators, because they convert a given eigenket of $\hat{I}_z$ into one with the eigenvalue increased or decreased, respectively, by one. In terms of these operators, we have

$$\hat{I}_x = \frac{1}{2}(\hat{I}_+ + \hat{I}_-), \quad \hat{I}_y = \frac{1}{2i}(\hat{I}_+ - \hat{I}_-) \quad (61)$$

The inverse relationship is

$$\hat{I}_+ = \hat{I}_x + i\hat{I}_y, \quad \hat{I}_- = \hat{I}_x - i\hat{I}_y \quad (62)$$

Applying these relations to equation (57) leads to a new basis:

$$\left. \begin{aligned} \hat{I}_+ &\rightarrow \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, & \hat{I}_- &\rightarrow \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix} \\ \hat{I}_z &\rightarrow \frac{1}{2} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}, & \hat{E} &\rightarrow \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \end{aligned} \right\} \quad (63)$$

The orthonormal basis corresponding to equation (58) is given by

$$\left. \begin{aligned} \hat{U}_1 &= \hat{T}_{0,0}^{(0)} = \frac{1}{\sqrt{2}} \hat{E} \rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \\ \hat{U}_2 &= \hat{T}_{0,0}^{(1)} = \sqrt{2} \hat{I}_z \rightarrow \frac{\sqrt{2}}{2} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \\ \hat{U}_3 &= \hat{T}_{1,0}^{(1)} = -\hat{I}_+ \rightarrow \begin{bmatrix} 0 & -1 \\ 0 & 0 \end{bmatrix} \\ \hat{U}_4 &= \hat{T}_{-1,0}^{(1)} = \hat{I}_- \rightarrow \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix} \end{aligned} \right\} \quad (64)$$

The $\hat{T}_{q,j}^{(k)}$ designation for these operators is that characterizing the *irreducible spherical tensor operators*. There will be

$2k + 1$ members in a set of operators of rank k with projection q ranging from $-k$ to k in integer steps. Note that the index j is not needed here, but will come into play when more complicated spin systems are considered with more than one set of operators of a given k . In what follows, the index j will be suppressed when it is not needed. It is easily verified that this basis is orthonormal. The minus sign associated with $\hat{U}_3$ does not affect the orthonormality of the set. It is common practice to choose this ‘phase factor’ to correspond to that of the spherical harmonic functions, i.e., such that

$$\hat{T}_q^{(k)\dagger} = (-1)^q \hat{T}_{-q}^{(k)} \quad (65)$$

The operators then satisfy equation (39) in the form

$$\text{Tr}(\hat{T}_q^{(k)} \hat{T}_{q'}^{(k)\dagger}) = (-1)^q \text{Tr}(\hat{T}_q^{(k)} \hat{T}_{-q'}^{(k)}) = \delta_{kk'} \delta_{q-q'} \quad (66)$$

The defining characteristic of the irreducible spherical tensor operators is that when they are subjected to a rotation of the coordinate system, they behave like the spherical harmonic functions, i.e., they transform to linear combinations of the set such that operators of differing k or j never mix:

$$\hat{R}(\phi, \theta, \chi) \hat{T}_{q,j}^{(k)} \hat{R}^{-1}(\phi, \theta, \chi) = \sum_{q'=-k}^k D_{q'q}^{(k)}(\phi, \theta, \chi) \hat{T}_{q',j}^{(k)} \quad (67)$$

The rotation operator $\hat{R}(\phi, \theta, \chi)$ and its inverse (defined by equation (68)) transform any operator from the original coordinate system $\{x, y, z\}$ into a new one $\{x', y', z'\}$:

$$\left. \begin{aligned} \hat{R}(\phi, \theta, \chi) &= \exp(-i\phi \hat{I}_z) \exp(-i\theta \hat{I}_y) \exp(-i\chi \hat{I}_z) \\ \hat{R}^{-1}(\phi, \theta, \chi) &= \exp(i\phi \hat{I}_z) \exp(i\theta \hat{I}_y) \exp(i\chi \hat{I}_z) \end{aligned} \right\} \quad (68)$$

The Euler angles $\{\phi, \theta, \chi\}$ define rotations about the z , then y , then z again axes of the original coordinate system, which rotations carry the original coordinate system to coincide with the new one. The $D_{q'q}^{(k)}(\phi, \theta, \chi)$ are called the *Wigner rotation matrix elements*. The definition of these coefficients is rather involved, and will not be given here. They are defined and tabulated in numerous texts, such as the excellent one by Zare.¹⁰ Exponential operators like those in equation (68) as generators of rotations play a central role in the theoretical development of NMR. They, too, are discussed in great detail in Zare’s text.

It was noted in Section 2.1 that operators do not necessarily commute. A special shorthand notation is commonly used for *commutators* of operators, defined as follows:

$$\hat{A}\hat{B} - \hat{B}\hat{A} \equiv [\hat{A}, \hat{B}] \quad (69)$$

Using this notation, an equivalent, though perhaps less intuitive, definition of irreducible spherical tensor operators is provided by the following commutation relations:

$$\left. \begin{aligned} [\hat{I}_{\pm}, \hat{T}_{q,j}^{(k)}] &= \{(k \mp q)(k \pm q + 1)\}^{1/2} \hat{T}_{q \pm 1, j}^{(k)} \\ [\hat{I}_z, \hat{T}_{q,j}^{(k)}] &= q \hat{T}_{q,j}^{(k)} \end{aligned} \right\} \quad (70)$$

Note that one is free to choose either the positive or the negative square root in the coefficient in equation (70), and the result will still satisfy both commutation relations. Thus, we choose the one that satisfies equation (65). The following commutators are easily verified for spin- $\frac{1}{2}$ from equation (63):

$$[\hat{I}_z, \hat{I}_{\pm}] = \pm \hat{I}_{\pm}, \quad [\hat{I}_{\pm}, \hat{I}_{\mp}] = \pm 2\hat{I}_z \quad (71)$$

From equation (59), using equation (62), one can generate the following operators and verify that equation (71) holds for spin 1 also:

$$\left. \begin{aligned} \hat{I}_+ &\rightarrow \sqrt{2} \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix}, \quad \hat{I}_- \rightarrow \sqrt{2} \begin{bmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} \\ \hat{I}_z &\rightarrow \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{bmatrix} \end{aligned} \right\} \quad (72)$$

It can be shown⁶ that these commutation relations are true in general. These three matrices represent an irreducible spherical tensor operator of rank one just as was the case for spin- $\frac{1}{2}$ in equation (64), and the zeroth-order operator can be written as well. Note, however, that the required normalization factors are different:

$$\left. \begin{aligned} \hat{T}_0^{(0)} &= \frac{1}{\sqrt{3}} \hat{E} \rightarrow \frac{1}{\sqrt{3}} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \\ \hat{T}_1^{(1)} &= -\frac{1}{2} \hat{I}_+ \rightarrow -\frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix} \\ \hat{T}_{-1}^{(1)} &= \frac{1}{2} \hat{I}_- \rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} \\ \hat{T}_0^{(1)} &= \frac{1}{\sqrt{2}} \hat{I}_z \rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{bmatrix} \end{aligned} \right\} \quad (73)$$

It is easily verified that these operators are orthonormal and satisfy equation (70).

Using these four operators as a starting point, the problem of finding the other five basis operators for spin 1 can now be addressed. The required operators must be mutually orthogonal and orthogonal to the four already proposed. A logical extension of what has been done so far would be the five elements of an irreducible spherical tensor operator of rank two. For spin 1, the step-up operator can be applied twice to the eigenstate $|-1\rangle$ to produce first the $|0\rangle$ then the $|1\rangle$ eigenstate. The corresponding second-rank operator is $\hat{I}_+ \hat{I}_+$. The representation of this operator can be obtained in several ways according to what we have learned so far. Perhaps the easiest way is to square the matrix given in equation (72) and normalize the result to give

$$\hat{T}_2^{(2)} = \frac{1}{2} \hat{I}_+ \hat{I}_+ \rightarrow \begin{bmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \quad (74)$$

which is easily shown to satisfy equation (70). Equation (70) can now be used to successively generate the other members of the set as follows:

$$[\hat{I}_-, \hat{T}_2^{(2)}] = \{(2+2)(2-2+1)\}^{1/2} \hat{T}_1^{(2)} = -2\hat{T}_1^{(2)} \quad (75)$$

The negative square root is chosen so as to satisfy equation (65). Hence, we have

$$\begin{aligned}\hat{T}_1^{(2)} &= -\frac{1}{2}[\hat{I}_-, \frac{1}{2}\hat{I}_+\hat{I}_+] = -\frac{1}{4}[\hat{I}_-, \hat{I}_+\hat{I}_+] \\ &= -\frac{1}{4}(\hat{I}_-\hat{I}_+\hat{I}_+ - \hat{I}_+\hat{I}_+\hat{I}_-) \end{aligned} \quad (76)$$

Then substituting from equation (71) yields

$$\begin{aligned}\hat{T}_1^{(2)} &= -\frac{1}{4}\{\hat{I}_-\hat{I}_+\hat{I}_+ - \hat{I}_+(2\hat{I}_z + \hat{I}_-\hat{I}_+)\} \\ &= -\frac{1}{4}\{(\hat{I}_-\hat{I}_+ - \hat{I}_+\hat{I}_-)\hat{I}_+ - 2\hat{I}_+\hat{I}_z\} \\ &= -\frac{1}{4}\{(-[\hat{I}_+, \hat{I}_-]\hat{I}_+ - 2\hat{I}_+\hat{I}_z\} \end{aligned} \quad (77)$$

Using equation (71) again gives the desired operator, and substitution from equation (72), gives the representation:

$$\hat{T}_1^{(2)} = \frac{1}{2}(\hat{I}_z\hat{I}_+ + \hat{I}_+\hat{I}_z) \rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & -1 \\ 0 & 0 & 0 \end{bmatrix} \quad (78)$$

Applying the same procedure successively generates the other three operators. The $q = 0$ component is

$$\begin{aligned}\hat{T}_0^{(2)} &= -\sqrt{\frac{1}{6}}[\hat{I}_-, \hat{T}_1^{(2)}] \\ &= -\frac{1}{2}\sqrt{\frac{1}{6}}[\hat{I}_-, (\hat{I}_z\hat{I}_+ + \hat{I}_+\hat{I}_z)] \\ &= -\frac{1}{2}\sqrt{\frac{1}{6}}(\hat{I}_-\hat{I}_z\hat{I}_+ - \hat{I}_z\hat{I}_+\hat{I}_- + \hat{I}_-\hat{I}_+\hat{I}_z - \hat{I}_+\hat{I}_z\hat{I}_-) \\ &= -\frac{1}{2}\sqrt{\frac{1}{6}}\{(\hat{I}_- + \hat{I}_z\hat{I}_-)\hat{I}_+ - \hat{I}_z\hat{I}_+\hat{I}_- + \hat{I}_-\hat{I}_+\hat{I}_z \\ &\quad - \hat{I}_+(-\hat{I}_- + \hat{I}_-\hat{I}_z)\} \\ &= -\frac{1}{2}\sqrt{\frac{1}{6}}(\hat{I}_+\hat{I}_- + \hat{I}_-\hat{I}_+ + \hat{I}_z[\hat{I}_-, \hat{I}_+] + [\hat{I}_-, \hat{I}_+]\hat{I}_z) \\ &= \sqrt{\frac{1}{6}}\{2\hat{I}_z^2 - \frac{1}{2}(\hat{I}_+\hat{I}_- + \hat{I}_-\hat{I}_+)\} \rightarrow \frac{1}{\sqrt{6}} \begin{bmatrix} 1 & 0 & 0 \\ 0 & -2 & 0 \\ 0 & 0 & 1 \end{bmatrix} \end{aligned} \quad (79)$$

In this case, the negative phase is chosen arbitrarily, because equation (65) places no constraint on the phase of this operator. The $q = -1$ component is

$$\begin{aligned}\hat{T}_{-1}^{(2)} &= \sqrt{\frac{1}{6}}[\hat{I}_-, \hat{T}_0^{(2)}] \\ &= \frac{1}{6}[\hat{I}_-, \{2\hat{I}_z^2 - \frac{1}{2}(\hat{I}_+\hat{I}_- + \hat{I}_-\hat{I}_+)\}] \\ &= \frac{1}{6}(2\hat{I}_-\hat{I}_z^2 - 2\hat{I}_z^2\hat{I}_- + \frac{1}{2}\hat{I}_+\hat{I}_-\hat{I}_- - \frac{1}{2}\hat{I}_-\hat{I}_-\hat{I}_+) \\ &= \frac{1}{6}\{2(\hat{I}_- + \hat{I}_z\hat{I}_-)\hat{I}_z - 2\hat{I}_z(-\hat{I}_- + \hat{I}_-\hat{I}_z) \\ &\quad + \frac{1}{2}(2\hat{I}_z + \hat{I}_-\hat{I}_+)\hat{I}_- - \frac{1}{2}\hat{I}_-(-2\hat{I}_z + \hat{I}_+\hat{I}_-)\} \\ &= \frac{1}{2}(\hat{I}_z\hat{I}_- + \hat{I}_-\hat{I}_z) \rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & -1 & 0 \end{bmatrix} \end{aligned} \quad (80)$$

Here the positive phase has been chosen to satisfy equation (65). The $q = -2$ component is

$$\begin{aligned}\hat{T}_{-2}^{(2)} &= \frac{1}{2}[\hat{I}_-, \hat{T}_{-1}^{(2)}] \\ &= \frac{1}{4}[\hat{I}_-, (\hat{I}_z\hat{I}_- + \hat{I}_-\hat{I}_z)] \\ &= \frac{1}{4}(-\hat{I}_z\hat{I}_-\hat{I}_- + \hat{I}_-\hat{I}_-\hat{I}_z) \\ &= \frac{1}{4}\{-(-\hat{I}_- + \hat{I}_-\hat{I}_z)\hat{I}_- + \hat{I}_-(\hat{I}_- + \hat{I}_z\hat{I}_-)\} \\ &= \frac{1}{2}\hat{I}_-\hat{I}_- \rightarrow \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{bmatrix} \end{aligned} \quad (81)$$

The positive phase has been chosen here, again arbitrarily. The same result could also be obtained by starting from $T_{-2}^{(2)}$ and stepping it up with I_+ . These nine operators given by equations (73), (74), and (78)–(81) form a complete basis set for spin 1. Of course, higher spin bases can be constructed in the same way; spin I will require irreducible spherical tensors of rank $k = 0, 1, 2, \dots, 2I$.

4 THE DENSITY OPERATOR

It is a familiar concept⁷ that an experimental measurement will yield a value corresponding to the bracket of the state of the system under study with the operator corresponding to the observable:

$$\langle \hat{O}(t) \rangle = \langle \psi(t) | \hat{O} | \psi(t) \rangle \quad (82)$$

The notation on the left-hand side carries some connotation that the operator is time-dependent, which need not be the case; the time dependence in this case is carried entirely in the state. Some authors use the notation $\langle \hat{O} \rangle(t)$ or some other variant to avoid possible ambiguity. We shall retain the notation of equation (82), trusting the reader to realize the subtle difference implied. This leads to a discussion of Schrödinger versus Heisenberg versus interaction pictures of quantum mechanics, which will be addressed in Section 4.1. Of course, this result is independent of the ‘picture’ employed or the basis chosen. Inserting twice the sum on projection operators for some basis as in equation (19) and rearranging yields

$$\begin{aligned}\langle \hat{O}(t) \rangle &= \langle \psi(t) | \sum_{i=1}^n |i\rangle \langle i| \hat{O} \sum_{j=1}^n |j\rangle \langle j| \psi(t) \rangle \\ &= \sum_{i,j=1}^n \langle \psi(t) | i \rangle \langle i | \hat{O} | j \rangle \langle j | \psi(t) \rangle \\ &= \sum_{i,j=1}^n \langle j | \psi(t) \rangle \langle \psi(t) | i \rangle \langle i | \hat{O} | j \rangle \end{aligned} \quad (83)$$

As in equation (9), the quantity $|\psi(t)\rangle \langle \psi(t)|$ can be regarded as an operator, which is known as the density operator $\hat{\rho}(t)$:

$$\hat{\rho}(t) = |\psi(t)\rangle \langle \psi(t)| \quad (84)$$

Continuing from equation (83), we can write

$$\begin{aligned}
 \langle \hat{O}(t) \rangle &= \sum_{i,j=1}^n \langle j | \hat{\rho}(t) | i \rangle \langle i | \hat{O} | j \rangle \\
 &= \sum_{j=1}^n \langle j | \hat{\rho}(t) \hat{O} | j \rangle \\
 &= \text{Tr}(\hat{\rho}(t) \hat{O})
 \end{aligned} \tag{85}$$

This is an important relationship showing that the expected value of any operator can be computed by taking the trace of its product with the density operator. This form is completely equivalent to equation (82), and is the form commonly used for discussion of magnetic resonance phenomena. Just as the state $|\psi(t)\rangle$ contains all that can be known about the state of a system, so does the density operator.

According to equation (42), using an appropriate operator basis, we can write

$$\begin{aligned}
 \hat{\rho}(t) &= \sum_{i=1}^{n^2} \text{Tr}[\hat{\rho}(t) \hat{U}_i^\dagger] \hat{U}_i \\
 &= \sum_{i=1}^{n^2} \langle \hat{U}_i^\dagger(t) \rangle \hat{U}_i
 \end{aligned} \tag{86}$$

Thus, the expected values of all the basis operators provide the coefficients needed to represent the density operator in any basis, and these values provide a Liouville space representation of the density operator according to equation (43). Extensive use of this concept will be made later in developing the equations needed to explain spin relaxation.

The development so far has implied that the system of interest can be characterized by a state $|\psi(t)\rangle$. Liquid samples can never be so characterized, but can often be viewed as an ensemble of such isolated systems. Thus, it is desirable to take an ensemble average of equation (84). Since all the variation among the members of the ensemble resides in the operator $|\psi(t)\rangle\langle\psi(t)|$, the averaging process commutes with the sums over basis states, and we can write

$$\begin{aligned}
 \overline{\langle \hat{O}(t) \rangle} &= \sum_{i,j=1}^n \overline{\langle j | \psi(t) \rangle \langle \psi(t) | i \rangle \langle i | \hat{O} | j \rangle} \\
 &= \sum_{i,j=1}^n \overline{\langle j | \hat{\rho}(t) | i \rangle \langle i | \hat{O} | j \rangle} \\
 &= \sum_{j=1}^n \langle j | \bar{\rho}(t) \hat{O} | j \rangle \\
 &= \text{Tr}\{\bar{\rho}(t) \hat{O}\}
 \end{aligned} \tag{87}$$

Clearly, $\hat{\rho}(t)$ can be replaced by $\bar{\rho}(t)$ in the above equations, leaving the form of the equations the same. In what follows, we shall not retain the overbar notation, but the density operator should be assumed to be averaged over an ensemble.

4.1 Time Evolution of the Density Operator

The time-dependent Schrödinger equation

$$i\hbar \frac{d}{dt} |\psi(t)\rangle = \hat{\mathcal{H}}(t) |\psi(t)\rangle \tag{88}$$

can easily be converted to our density operator formalism. Beginning from equation (84) and using equation (88) and its complex conjugate obtained using equations (2) and (7), we can write

$$\begin{aligned}
 \frac{d\hat{\rho}(t)}{dt} &= \frac{d}{dt} \{ |\psi(t)\rangle \langle \psi(t)| \} \\
 &= \frac{d}{dt} \{ |\psi(t)\rangle \} \langle \psi(t)| + |\psi(t)\rangle \frac{d}{dt} \{ \langle \psi(t)| \} \\
 &= -\frac{i}{\hbar} \hat{\mathcal{H}}(t) |\psi(t)\rangle \langle \psi(t)| + \frac{i}{\hbar} |\psi(t)\rangle \langle \psi(t)| \hat{\mathcal{H}}(t) \\
 &= -\frac{i}{\hbar} \{ \hat{\mathcal{H}}(t) \hat{\rho}(t) - \hat{\rho}(t) \hat{\mathcal{H}}(t) \} \\
 &= -\frac{i}{\hbar} [\hat{\mathcal{H}}(t), \hat{\rho}(t)]
 \end{aligned} \tag{89}$$

Note that the Hamiltonian is Hermitian. The commutator of the Hamiltonian with the density operator determines the time development of the density operator. This relation is referred to as the *Liouville–von Neuman equation*, and will play a central role in what follows. Our goal, generally stated, will be to find solutions of this equation using a Hamiltonian corresponding to various experimental situations. The density operator at some particular time will generally be known—at least parametrically—and equation (89) must then be integrated to obtain the time development of the density operator.

The solution of this equation of motion is fairly simple if the Hamiltonian is not time-dependent. If we suppose that the density operator has the value $\hat{\rho}(0)$ at $t = 0$ then

$$\hat{\rho}(t) = \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\rho}(0) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \tag{90}$$

is a solution, as can be verified by differentiation:

$$\begin{aligned}
 \frac{d\hat{\rho}(t)}{dt} &= \left(-\frac{i}{\hbar} \hat{\mathcal{H}}\right) \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\rho}(0) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \\
 &\quad + \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\rho}(0) \left(\frac{i}{\hbar} \hat{\mathcal{H}}\right) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \\
 &= -\frac{i}{\hbar} \left\{ \hat{\mathcal{H}} \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\rho}(0) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \right. \\
 &\quad \left. - \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\rho}(0) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\mathcal{H}} \right\} \\
 &= -\frac{i}{\hbar} \{ \hat{\mathcal{H}} \hat{\rho}(t) - \hat{\rho}(t) \hat{\mathcal{H}} \} = -\frac{i}{\hbar} [\hat{\mathcal{H}}, \hat{\rho}(t)]
 \end{aligned} \tag{91}$$

We have used the fact that an operator commutes with a function of itself.

Now let us examine the expected value of a generic operator with this solution. Substituting equation (90) into equation (87) yields

$$\begin{aligned}
 \langle \hat{O}(t) \rangle &= \text{Tr}\{\hat{\rho}(t) \hat{O}\} = \text{Tr}\left\{ \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\rho}(0) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{O} \right\} \\
 &= \text{Tr}\left\{ \hat{\rho}(0) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{O} \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \right\} \\
 &= \text{Tr}\{\hat{\rho}(0) \hat{O}(t)\}
 \end{aligned} \tag{92}$$

The fact that the trace operation is invariant under cyclic permutation of the factors has been used, and the time-dependent operator $\hat{O}(t)$ has been introduced according to

$$\hat{O}(t) = \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}t\right) \hat{O} \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}t\right) \quad (93)$$

Equation (87) expresses the Schrödinger picture of quantum mechanics, whereas equation (92) transforms into the Heisenberg picture. Clearly, the two forms are equivalent.

Differentiating equation (93) yields the equation of motion for the time-dependent operators of the Heisenberg picture, corresponding to equation (89) for the Schrödinger picture:

$$\frac{d\hat{O}(t)}{dt} = \frac{i}{\hbar}[\hat{\mathcal{H}}, \hat{O}(t)] \quad (94)$$

The derivation proceeds like that of equation (91). The equations for the Schrödinger and the Heisenberg pictures are similar in form, but the sign differences in the various terms should be noted.

When the Hamiltonian is time-dependent, the situation is considerably more complex, and no attempt will be made here to discuss this case in general terms. However, suppose the Hamiltonian can be separated into a term that is time-dependent and another that is not:

$$\hat{\mathcal{H}}(t) = \hat{\mathcal{H}}_0 + \hat{\mathcal{H}}_1(t) \quad (95)$$

Equation (89) may then be rewritten as

$$\begin{aligned} \frac{d\hat{\rho}(t)}{dt} &= -\frac{i}{\hbar}[\hat{\mathcal{H}}_0 + \hat{\mathcal{H}}_1(t), \hat{\rho}(t)] \\ &= -\frac{i}{\hbar}\{[\hat{\mathcal{H}}_0, \hat{\rho}(t)] + [\hat{\mathcal{H}}_1(t), \hat{\rho}(t)]\} \end{aligned} \quad (96)$$

If $\hat{\mathcal{H}}_1(t) = 0$ then the solution is as in equation (90). By analogy with equation (90), let us define the transformed operators

$$\hat{\rho}'(t) = \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \hat{\rho}(t) \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \quad (97)$$

$$\hat{\mathcal{H}}_1'(t) = \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \hat{\mathcal{H}}_1(t) \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \quad (98)$$

Differentiating equation (97) and substituting from equations (96) and (98) then gives

$$\begin{aligned} \frac{d\hat{\rho}'(t)}{dt} &= \frac{i}{\hbar}\hat{\mathcal{H}}_0 \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \hat{\rho}(t) \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \\ &\quad + \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \frac{d\hat{\rho}(t)}{dt} \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \\ &\quad + \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \hat{\rho}(t) \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0\right) \\ &= \frac{i}{\hbar}[\hat{\mathcal{H}}_0, \hat{\rho}'(t)] + \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \left(-\frac{i}{\hbar}\{[\hat{\mathcal{H}}_0, \hat{\rho}(t)]\right. \\ &\quad \left.+ [\hat{\mathcal{H}}_1(t), \hat{\rho}(t)]\}\right) \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \\ &= -\frac{i}{\hbar}[\hat{\mathcal{H}}_1'(t), \hat{\rho}'(t)] \end{aligned} \quad (99)$$

Thus, in this ‘interaction picture’, part of the time dependence is placed in the operators and part remains in the density operator. The effect of $\hat{\mathcal{H}}_0$ appears only implicitly in the exponential transformation operator. Of course, this is not a solution of the equation of motion, but it will prove to be a useful technique to be applied later on.

4.2 The Reduced Density Operator

In NMR experiments, it is usually the case that the nuclear spins interact weakly with the other degrees of freedom of the sample of interest. For the moment, let us assume that they do not interact at all. The state of the system can be written as a direct product, as in equation (48a), of a ket corresponding to the spin degrees of freedom with one corresponding to the rest of the system, the lattice:

$$|S\rangle|L\rangle = |SL\rangle \quad (100)$$

The number of degrees of freedom, i.e., the number of basis states, necessary to span the spins is modest, while that necessary to span the lattice is very large—effectively infinite.

Consider the expected value of an operator that acts only on the spin degrees of freedom. If $\{|s\rangle\}$ is a basis set spanning both the spins and the lattice, we can write

$$\begin{aligned} \langle\hat{O}\rangle &= \text{Tr}(\hat{\rho}\hat{O}) = \text{Tr}(|SL\rangle\langle SL|\hat{O}) \\ &= \sum_{sl} \langle sl|SL\rangle\langle SL|\hat{O}|sl\rangle \end{aligned} \quad (101)$$

Since $\hat{O}$ commutes with the lattice operators, this can be rearranged to yield

$$\begin{aligned} \langle\hat{O}\rangle &= \sum_s \langle s|S\rangle\langle S|\hat{O}|s\rangle \sum_l \langle l|L\rangle\langle L|l\rangle \\ &= \sum_s \langle s|S\rangle \left(\sum_l \langle l|L\rangle\langle L|l\rangle \right) \langle S|\hat{O}|s\rangle \end{aligned} \quad (102)$$

We can now define the reduced density operator by

$$\hat{\sigma} = |S\rangle \left(\sum_l \langle l|L\rangle\langle L|l\rangle \right) \langle S| = \text{Tr}_l(\hat{\rho}) \quad (103)$$

The expected value of $\hat{O}$ can then be written as

$$\langle\hat{O}\rangle = \text{Tr}_s(\hat{\sigma}\hat{O}) \quad (104)$$

Thus, observing experimental quantities corresponding to spin operators requires only a knowledge of this reduced density operator, and the problem has, at least in principle, only the small dimensionality of the spin degrees of freedom and not the very large dimensionality of the spins and the lattice. In particular, the Liouville equation, equation (99), can be cast in this form. However, if there were, indeed, no interaction of the spins with the lattice, as was assumed above, there would be no relaxation. Of course, this is observed not to be the case, but the interaction is sufficiently weak that it can be treated by perturbation methods, and the very large number of

degrees of freedom in the lattice permits treating the lattice classically to achieve excellent correspondence of theory to experiment. In what follows, then, solutions will be sought of the Liouville–von Neuman equation for the reduced density operator:

$$\frac{d\hat{\sigma}(t)}{dt} = -\frac{i}{\hbar}[\hat{\mathcal{H}}(t), \hat{\sigma}(t)] \quad (105)$$

5 SUPEROPERATORS

The representation of operators in Liouville space has been discussed in Section 2.2. In this section, we shall introduce superoperators that act on operators in Liouville space in much the same way as operators act on states in Hilbert space, i.e., superoperators transform one operator into another.

Consider the operator product

$$\hat{C} = \hat{B}_1 \hat{A} \hat{B}_2 \quad (106)$$

Let us attempt to cast $\hat{A}$ in a Liouville space representation and then find a superoperator $\hat{B}$ such that $|\hat{C}\rangle = \hat{B}|\hat{A}\rangle$. The operator product can be written as follows and rearranged as shown by applying equations (7) and (15):

$$\begin{aligned} \langle i|\hat{C}|j\rangle &= \sum_{k,l=1}^n \langle i|\hat{B}_1|k\rangle \langle k|\hat{A}|l\rangle \langle l|\hat{B}_2|j\rangle \\ &= \sum_{k,l=1}^n \langle i|\hat{B}_1|k\rangle \langle j|\hat{B}_2^\dagger|l\rangle \langle k|\hat{A}|l\rangle \end{aligned} \quad (107)$$

The superoperator matrix elements can now be defined by

$$\langle ij|\hat{B}|kl\rangle = \langle i|\hat{B}_1|k\rangle \langle j|\hat{B}_2^\dagger|l\rangle \quad (108)$$

This expression can be viewed as the matrix elements of a direct product in a space with basis $|i\rangle|j\rangle = |ij\rangle$, the direct product of two identical Hilbert space bases as in equation (50):

$$\hat{B} = \hat{B}_1 \otimes \hat{B}_2^\dagger \quad (109)$$

The matrix elements of $\hat{A}$ may be mapped into a vector in this same space just as in equation (43). In fact, the operator basis $\{\hat{U}_i\}$ introduced in equation (43) is equivalent to the basis $\{|ij\rangle\}$. The matrix elements of $\hat{A}$ may be written as

$$\langle ij|\hat{A}\rangle = \langle i|\hat{A}|j\rangle \quad (110)$$

Then equation (107) can be written as

$$|\hat{C}\rangle = \hat{B}|\hat{A}\rangle \quad (111)$$

The utility of this formalism is evident from several examples.

5.1 Unitary Transformations

Unitary transformations like $\hat{U}\hat{A}\hat{U}^\dagger$ in Hilbert space can easily be translated to Liouville space using equation (109) to define the relevant superoperator

$$\hat{\hat{U}} = \hat{U} \otimes \hat{U} \quad (112)$$

Note that $(\hat{U}^\dagger)^\dagger = \hat{U}$. Then the unitary transformation becomes

$$\hat{\hat{U}}|\hat{A}\rangle \quad (113)$$

The superoperator $\hat{\hat{U}}$ is unitary. To show this, we can write

$$\hat{A} = \hat{U}^\dagger \hat{U} \hat{A} \hat{U}^\dagger \hat{U} \quad (114)$$

But this implies

$$|\hat{A}\rangle = (\hat{U}^\dagger \otimes \hat{U}^\dagger)(\hat{U} \otimes \hat{U})|\hat{A}\rangle = \hat{\hat{U}}^\dagger \hat{\hat{U}}|\hat{A}\rangle \quad (115)$$

where the second equality in equation (115) follows immediately by considering the adjoint of equation (108). Thus, it must be that

$$\hat{\hat{U}}^\dagger \hat{\hat{U}} = \hat{E} \quad (116)$$

5.2 Commutators

Consider the commutator $[\hat{A}, \hat{B}]$ as the action of something denoted by $[\hat{A},]$ on the operator $\hat{B}$ to produce a new operator $\hat{C}$. This relationship can be written as

$$[\hat{A}, \hat{B}] = \hat{A}\hat{B} - \hat{B}\hat{A} = \hat{A}\hat{B}\hat{E} - \hat{E}\hat{B}\hat{A} \quad (117)$$

Applying equation (109) then yields

$$\hat{\hat{A}} = \hat{A} \otimes \hat{E} - \hat{E} \otimes \hat{A}^\dagger \quad (118)$$

5.3 The Liouvillian

Using equation (118), the equation of motion for the density operator equation (89) can be re-written as

$$\frac{d|\hat{\rho}(t)\rangle}{dt} = -\frac{i}{\hbar}\hat{\hat{\mathcal{L}}}(t)|\hat{\rho}(t)\rangle \quad (119)$$

The Liouvillian superoperator corresponding to the commutator with the Hamiltonian is defined as

$$\hat{\hat{\mathcal{L}}}(t) = \hat{\mathcal{H}}(t) \otimes \hat{E} - \hat{E} \otimes \hat{\mathcal{H}}(t) \quad (120)$$

Note that the Hamiltonian is Hermitian, so that $\hat{\mathcal{H}}(t) = \hat{\mathcal{H}}(t)^\dagger$.

1 INTRODUCTION

Proton (or other spin- $\frac{1}{2}$ nuclei) NMR spectra of molecules dissolved in liquid crystalline solvents differ from their isotropic analogues in a significant way. Thus, the well-known proton isotropic spectrum of ethylbenzene (composed of a triplet, a quadruplet and a broad singlet) changes into the ugly looking spectrum shown in Figure 1. Only by displaying the spectrum with a much smaller Hz/cm ratio is it possible to recognize the few thousand closely spaced, well-resolved, single transitions dispersed over a range of a few kilohertz which compose the spectrum. For molecules with a higher number of interacting spins the situation is even worse; the total intensity is dispersed over so many closely spaced, single transitions that their anisotropic spectra, except for a few highly symmetric spin systems, appear as a single unresolved band a few kilohertz in width. For this reason it is not necessary to use deuterated compounds as anisotropic solvents because the liquid crystalline phases used contain more than 20 interacting protons and contribute to the total spectrum only as the lumps and bumps which form the baseline. The lines due to the solute, which are much more intense because their total intensity is dispersed over relatively fewer transitions, can be distinguished from the baseline.¹

These differences arise because two extra terms have to be considered in the anisotropic Hamiltonian.¹ Within the usual high field approximation the Hamiltonian is given by

$$\begin{aligned} \hat{\mathcal{H}} = & \frac{1}{2\pi} \sum_i \gamma_i \hat{I}_{iz} (1 - \sigma_i^{\text{iso}} - \bar{\sigma}_{zzi}) B_z \\ & + \sum_{i < j} \{ J_{ij}^{\text{iso}} [\hat{I}_{iz} \hat{I}_{jz} + \frac{1}{2} (\hat{I}_i^+ \hat{I}_j^- + \hat{I}_i^- \hat{I}_j^+)] \} \\ & + \sum_{i < j} [\bar{J}_{zzij} + 2\bar{D}_{zzij}] [\hat{I}_{iz} \hat{I}_{jz} - \frac{1}{2} (\hat{I}_i^+ \hat{I}_j^- + \hat{I}_i^- \hat{I}_j^+)] \\ & + \sum_i \frac{\bar{q}_{zzi}}{4I_i(2I_i - 1)} [3\hat{I}_{iz} \hat{I}_{iz} - I_i(I_i + 1)] \end{aligned} \quad (1)$$

where γ_i is the magnetogyric ratio of the i th nucleus. The fourth term is included only if $I_i \geq 1$, while the σ_i^{iso} and J_{ij}^{iso}

Figure 1 300 MHz (7.06 T) proton spectrum of ethylbenzene dissolved in ZLI 1132, a nematic solvent obtained from Merck

scalars, the trace of the σ shielding and J indirect spin–spin coupling tensors, are the well-known spectral parameters which determine isotropic spectra; $\bar{\sigma}_{zzi}$, $\bar{J}_{zzij}$, $\bar{D}_{zzij}$ and $\bar{q}_{zzi}$ are the averaged components of the shielding, indirect coupling, direct dipolar coupling, and quadrupolar coupling tensors, respectively. The last two tensors have a null trace and so do not influence the frequencies or intensities of the peaks in isotropic spectra.

The direct dipolar couplings are related to the molecular geometries by

$$\bar{D}_{zzij} = K_{ij} \sum_{\alpha\beta} G_{ij\alpha\beta} S_{\alpha\beta}, \quad \alpha, \beta = x, y, z \quad (2)$$

for rigid molecules, or

$$\bar{D}_{zzij} = K_{ij} \sum_n p^n \sum_{\alpha\beta} G_{ij\alpha\beta}^n S_{\alpha\beta}^m \quad (3)$$

if internal rotational motions are present. K_{ij} depends on the magnetogyric ratio of the i th and j th nuclei, p^n is the population of conformer n , $S_{\alpha\beta}^m$ are the elements of $\mathbf{S}^n$, the Saupe orientational matrix for conformer n , $G_{ij\alpha\beta}^n$ are related to the internuclear distance r_{ij} and to its orientation with respect to a Cartesian system x, y, z fixed on the molecule.

It should be noted that the observed differences are not just due to the extra parameters present, but also, and more importantly, to the wider range of values that they can assume (from 2.5 to -5 kHz for direct couplings, and up to several kilohertz for quadrupolar couplings). If spin systems composed of only spin- $\frac{1}{2}$ nuclei are considered (for a description of how quadrupolar couplings influence anisotropic spectra, see *Liquid Crystalline Samples: Deuterium NMR*), the fourth term in equation (1) is zero and the spectrum shape depends mainly on the values of the dipolar couplings. Two important consequences ensue from this fact: (a) all the nuclei in the molecule have dipolar couplings larger than the experimental linewidth (4–5 Hz); and (b) no first-order features are present in the spectra of homonuclear spin systems.

Two points follow from equation (1). First, the direct spin–spin coupling $\bar{D}_{zzij}$ cannot be measured separately from $\bar{J}_{zzij}$ because only the quantity

$$\bar{T}_{zzij} = \bar{D}_{zzij} + \frac{1}{2} \bar{J}_{zzij} \quad (4)$$

can be determined experimentally,^{1c} and so liquid crystal NMR can be used to determine the geometry only if the pseudodipolar couplings $\bar{J}_{zzij}$ are known independently. Experimental and theoretical studies have shown that the pseudodipolar term is usually much smaller than the dipolar coupling and so, with the exception of F–F couplings, $\bar{D}_{zzij}$ can be safely equated to $\bar{T}_{zzij}$ (see *Anisotropy of Shielding and Coupling in Liquid Crystalline Solutions*).

The second point involves magnetically equivalent nuclei (see *Magnetic Equivalence*). The frequencies and intensities in isotropic spectra do not depend on the values of the indirect couplings between nuclei belonging to the same magnetically equivalent group, but this is not the case for anisotropic spectra. In many spectra this just means that there is one more direct coupling for each magnetically equivalent group to be taken into account in anisotropic spectral analysis, but the effects are quite dramatic for A_n (where n is the number of interacting spins) spin systems. Benzene is a very good example; all six protons have the same chemical shift and so, even though there are three different indirect couplings (J_{ortho} , J_{meta} , and J_{para}), the isotropic spectrum shows only a single transition. The spin system is correctly defined as A_6 . The spectrum of benzene dissolved in an orienting medium will instead contain a maximum of 72 lines and is analyzable in terms of a chemical shift and three indirect and three direct couplings. The correct notation for the spin system is $AA'A''A'''A''''A'''''$.^{1b}

2 COMPUTER PROGRAMS FOR SPECTRAL ANALYSIS

For anisotropic spectra, analytical solutions are possible only for a very limited number of simple spin systems,^{1a,1b} but simulation/iteration programs are available for spectral analysis. These programs will: (a) calculate the spectrum from a trial starting set of spectral parameters using the spin Hamiltonian in equation (1); and (b) refine the parameters to fit some spectral quantities.²

A few methods have been proposed which use different spectral quantities in the fit, but only three of them have found application in anisotropic spectral analysis.

1. *Fully automated analysis*³ According to this approach the full spectrum (defined by a vector containing intensity values at a fixed frequency interval) is used in the iteration procedure. No operator intervention is needed during the iteration cycles; at the end of the procedure the operator checks if the experimental spectrum has been reproduced correctly and no false minimum found (for a more detailed description of the method and computer programs, see *Analysis of Spectra: Automatic Methods*).
2. *Swalen–Reilly method*⁴ The ‘experimentally’ determined energy level diagram (ELD) is used in the refinement program NMRIT.^{2,4b} The final parameter set, refined assuming a given assignment of calculated to experimental levels, is used to calculate the spectrum which is then compared with the experimental one. The procedure is repeated for a different assignment and the parameters giving the best fit between the calculated and experimental spectrum are assumed to be correct. The procedure can be easily automated, its main advantage deriving from

the relatively low number of distinct assignments.⁵ The algorithm which computes the ELD [part (a) of the program] must take into account the correct symmetry of the spin system.

3. *Castellano–Bothner-By method*⁶ By far the most widely used approach,² this method makes use of the experimental frequencies in the parameters’ refinement procedure. The method is particularly attractive because the derivatives

$$\frac{\partial F_{mn}}{\partial p_j} = \frac{\partial \Lambda_m}{\partial p_j} - \frac{\partial \Lambda_n}{\partial p_j} \quad (5)$$

where p_j is the j th spectral parameter, Λ_m is the m th eigenvalue, and F_{mn} is the calculated frequency of the transition between the m th and n th levels, can be calculated analytically. In fact,

$$\frac{\partial \Lambda_m}{\partial p_j} = \left(\mathbf{U} \frac{\partial \mathbf{H}}{\partial p_j} \mathbf{U} \right)_{mm} \quad (6)$$

where $\mathbf{U}$ is the matrix which diagonalizes the Hamiltonian matrix representation $\mathbf{H}$ in a given basis set. Care must be taken when choosing the basis set, in order to make as simple as possible the algorithm which computes the matrix $(\partial \mathbf{H} / \partial p_j)$.

Line identification numbers from a spectrum calculated with a trial, starting set of spectral parameters are assigned by the operator to experimental frequencies; the program will modify a selected subset of parameters to minimize the root mean square (rms) of the differences between the assigned calculated and experimental frequencies and will output the spectrum calculated with the new parameter set. The operator will compare the two spectra, recognize more lines to assign, modify or delete old assignments and choose a new subset of parameters to iterate. The cycles will be repeated until nearly all the experimental lines are assigned and a low rms obtained, having iterated the whole set of spectral parameters. The procedure is cumbersome, requiring a great deal of time and effort by the operator in the assignment step, and cannot be easily automated because only the operator can discriminate between the $N!$ different assignments (N being the number of observed transitions) on the basis of their intensities and relative positions. The probability of achieving success in the spectral analysis is low, decreases quickly as the complexity of the spin system increases, and is strictly related to the quality of the starting set, i.e. how near the starting parameter values are to the final ones.

To reduce the computational requirements [central processing unit (CPU) time and storage requirements] of part (a) of the program, much effort has been devoted to making full use of the possibilities of simplifying the Hamiltonian by using suitable basis function sets, but keeping operational the Castellano–Bothner-By iterative method. The first programs (LAOCOON^{6b} and its anisotropic counterpart LAOCONOOR) took into account the so-called Fz and X approximation factorization; magnetic equivalence factorization based on the Ferguson–Marquardt formalism⁷ (composite particle formalism) was introduced in the LEQUOR program⁸ in the early 1970s.

Molecular symmetry can also be used to factorize the Hamiltonian matrix if the basis function sets which are used belong to the irreducible representation of the permutation

group of the spin system.² This leads to an increase in the complexity of the algorithm which computes: (i) the elements of the Hamiltonian and transition probability matrices, and (ii) the analytical derivatives ($\partial \mathbf{H} / \partial p_i$) in the basis set used. However, computational efficiency is greatly increased. Simulation programs which make full use of molecular symmetry exist,⁹ but the iterative part has been implemented only for the C_2 permutation group (program LACX^{2,10}).

The two formalisms (composite particle and symmetry factorization) have been combined in the ARCANA program,¹¹ which has been used to analyze such complex spin systems as those arising from the 11 protons in 4-methoxy-4'-cyanobiphenyl¹² (an AA'BB'CC'DD'E₃ spin system).

CPU times can be further reduced if more efficient ordering routines are used. The gain is quite impressive for complex spin systems, resulting in the astonishingly short time of 2 min when a Shell-Metzner ordering¹³ routine was used. This compares with 102 min for the commonly used Bubble-Sort¹³ for the AA'BB'CC'XX'Y₃ ($I_A = I_B = I_C = \frac{1}{2}$, $I_X = I_Y = 1$) spin system which gives more than 10 000 transitions, and was simulated on a VAX 11/780¹⁴ using the ARCANA program. More efficient diagonalization routines give better total performance in the simulation step, but some problems arise when they are used in the iterative step. In fact, depending on the diagonalization algorithm used, pairs of eigenvalues can change their positions arbitrarily; the line numbers change in an unpredictable way and the iteration fails. Rough prediagonalization, according to Castellano et al.,^{6a} can eliminate this inconvenience if Jacobi based diagonalization routines are used.

Computer hardware is now improving at such a fast rate that the latest generation of workstations have performances in terms of mips (million instructions per second), main memory and mass storage, which are similar to, if not greater, than the largest mainframes of 10 years ago. In fact, the most important differences between programs is not now in their efficiency in simulating the spectra, or even in the iteration procedure, but rather in their ability to produce a visual representation of the spectrum on the terminal, and in the ease of assigning transitions to observed frequencies.

3 OBTAINING STARTING PARAMETERS FOR ITERATIONS

Remembering the wide range of allowed values of D_{ij} , it is easy to understand the enormous difficulties faced in analyzing anisotropic spectra. When the line density in the spectrum is low (few nuclei, strongly oriented spin systems), very approximate estimates of the D_{ij} values can quite easily give frequency/intensity patterns in the calculated spectra that can be recognized in the experimental spectra. When the spectra become crowded (the one shown in Figure 1 is a good example), a completely random trial-and-error approach is hopeless; more systematic and efficient methods have to be devised to ensure at least some probability of success in the analysis. Sometimes the spectral parameters can be guessed either from a comparison with data for similar molecules (or the same molecule in a different solvent) or from the shape of the spectrum.

The spectra of the pyridine-I₂ complex¹⁵ shown in Figure 2 illustrate this point very well. At high concentrations

Figure 2 100 MHz (2.34 T) proton spectra of [¹⁴N]pyridine in phase IV (Merck); the quantity of added I₂ increases from the top (0 mol% with respect to pyridine) to the bottom (60 mol%). The axis of highest order is perpendicular to the ring for free pyridine, parallel to the N-I-I direction for the complex. (Reproduced by permission of Royal Chemical Society from D. Catalano, C. A. Veracini, P. L. Barili, and M. Longeri, *J. Chem. Soc., Perkin Trans. II*, 1983, 171)

of the complex, the spectrum looks fairly simple, displaying even some first-order features such as the pentuplet-like multiplet in the center of the spectrum. The two outer groups can then be thought to be due to the *ortho* and *meta* protons, the distance between the groups being related to the D_{om} coupling, while the spacing between two consecutive lines in the central multiplet is equal to $D_{op} + D_{mp}$. In addition, the chemical shifts can be guessed approximately. This behavior is due to the fact that the molecule is strongly oriented with its molecular long axis tending to lie parallel to the mesophase director. When this happens, D_{om} has a large negative value (below -1000 Hz), while both D_{op} and D_{mp} are, in absolute value, much smaller. (Note that the *ortho*-*meta* and *meta*-*para* distances are nearly the same but the direction of the interproton vector with respect to the director is very different.) For pyridine, where the N-*para*-proton axis is, on average, perpendicular to the mesophase

director, the spectrum is featureless, and no estimates of spectral parameters can be made.

A more general strategy is to prepare a solution of the fully protonated and perdeuterated isotopomers. The $S_{\alpha\beta}$ obtained from the analysis of the ^2H spectra (see *Liquid Crystalline Samples: Deuterium NMR*) can be used to calculate approximate dipolar couplings from trial structures. The method works fairly well for rigid molecules, but it is not so efficient when internal rotation motions are present in the molecule (see *Liquid Crystalline Samples: Structure of Nonrigid Molecules*). Examples of this approach are the analysis of the ^1H spectra of biphenyl¹⁶ and 4-cyanobiphenyl.¹⁷

Alternatively, keeping an approximate molecular structure constant, it is possible to iterate over the $S_{\alpha\beta}$ values. Because the number of the variables is small (usually two or three), the approximate solution is quickly found.¹⁸ The final parameter set is then obtained by iterating over the dipolar couplings independently.

As soon as the number of interacting spins increases, such simple considerations can no longer be applied. Monosubstituted benzenes display a behavior similar to the one already described. When the substituent does not contain protons, its spectrum looks like the one at the bottom of Figure 2, but if some interacting nucleus is present the complexity of the spectrum increases in two ways: (i) the number of the transitions increases because of the extra couplings; and (ii) groups of transitions due to these nuclei can overlap with some of the features due to the aromatic protons. This is precisely what happens for the spectrum of anisole, where the OCH_3 transitions fall in the same spectral region as the *para* proton.¹⁹

If these extra nuclei have different magnetogyric ratios only point (i) has to be taken into account, and first-order features due to the couplings between nuclei with different magnetogyric ratios appear in the spectrum. Such is the case for trideuteromethoxybenzene²⁰ (anisole- d_3) for example, where each transition of the aromatic protons is split into a septet: the septets in the outer wings are spaced by a distance approximately equal to the sum of the *ortho*- CD_3 and *meta*- CD_3 couplings, whilst the central septets are spaced by the *para*- CD_3 coupling. Being able to recognize all these structures in the spectrum, makes it possible to obtain very good values for the extra couplings and, in addition, to obtain the 'decoupled' spectrum due to the aromatic protons by selecting the central lines of each multiplet. What is left to be analyzed is just a five-spin $\text{AA}'\text{BB}'\text{C}$ system, the spectrum of which would look like the one shown at the bottom of Figure 2. Such a spectrum can be analyzed easily. This is the case for anisole dissolved in ZLI 1115; the spectrum in I35 showed very few septet structures, and so it was not possible to determine the 'decoupled' $\text{AA}'\text{BB}'\text{C}$ spin system.²⁰

A similar approach proved to be possible for the four-proton, six-deuterium $\text{AA}'\text{A}''\text{A}'''\text{X}_3\text{X}'_3$ spin system of 1,4-bis(trideuteromethoxy)benzene.¹¹ The proton spectrum is composed of two complex, well-spaced groups of lines, the spacing of which is related to the coupling between the two *ortho* aromatic protons. The $\text{AA}'\text{A}''\text{A}'''$ spin subsystem would give the very simple spectrum shown in Figure 3, according to that obtained for symmetrically *para*-disubstituted halobenzenes. Each line would then be split into 13 subspectra corresponding to the values of m_T , the total deuteron spin quantum number, by coupling with the six deuterons: for $m_T = \pm 6, \pm 5, \pm 4,$

Figure 3 Sketch of the spectrum of an $\text{AA}'\text{A}''\text{A}'''$ system of spin-1/2 nuclei with dipolar coupling constants typical for a *para*-homodisubstituted benzene, showing how transitions are connected. (Reproduced by permission of Royal Chemical Society from J. W. Emsley, D. L. Turner, A. Giroud, and M. Longeri, *J. Chem. Soc., Faraday Trans. 2*, 1985, **81**, 603)

$\pm 3, \pm 2, \pm 1$, and 0, the intensities would be 1, 6, 21, 50, 90, 126, and 141, respectively. Trying to recognize all the 13 subspectra by eye is hopeless; in this case the task was easily accomplished by doing a two-dimensional homonuclear correlation experiment.

For an $\text{AA}'\text{A}''\text{A}'''$ spin system spectrum, such as the one shown in Figure 3, only two lines (the most intense ones) within the two groups share the same energy level, all the other connections being between symmetric lines belonging to the different groups. As a consequence, the off-diagonal peaks near the diagonal reveal the position of the two connected lines in each subspectrum. As shown in Figure 4, only 8 of the 13 off-diagonal peaks expected on each side of the main diagonal are visible. The lines belonging to the $m_T = 0$ subspectrum were easily spotted and then, with little effort, nearly all the subspectra (the less intense lines of the $m_T = \pm 6$ subspectra are lost in the noise) were recognized.

Such elegant ways of analyzing anisotropic spectra are quite uncommon. Very often spectral analysis is an unglamorous, boring, and long task, with many unrewarding days spent in front of a terminal with little or no hope of disentangling patterns that can be recognized from the maze of lines in the experimental spectrum and few exciting moments occur when the lines begin to assume the right frequency and intensity pattern and the main features appear in the calculated spectrum.

4 STRATEGIES IN SPECTRAL ANALYSIS

Two main strategies have been developed to try to simplify the analysis of spectra: one is aimed mainly at reducing human

Figure 4 200 MHz (4.69 T) proton autocorrelation spectrum of 4-bis(trideuteromethoxy)benzene dissolved in the liquid crystal PCH 1132 (Merck). (Reproduced by permission of Royal Chemical Society from J. W. Emsley, D. L. Turner, A. Giroud, and M. Longeri, *J. Chem. Soc., Faraday Trans. 2*, 1985, **81**, 603)

intervention by using automated methods, and the other is aimed at simplifying spectral analysis by obtaining simpler experimental spectra.

4.1 Fully Automated Approaches

Two different approaches use the first strategy. The first approach (mentioned previously) has been used to analyze the anisotropic spectra of three allyl halides²¹ and of cyclopentene,²² an eight-spin system. The second approach makes use of the Swalen–Reilly iterative method. The use of the latter method is limited, mainly because an ‘experimental’ ELD is needed. Programs and/or experimental methods devoted to this task have been proposed,² but the complexity and peculiar characteristics of anisotropic spectra make them unsuitable candidates for analysis in this way. Pfändler and Bodenhausen⁵ have proposed a two-dimensional z correlation spectroscopy (z COSY) experiment for constructing experimentally the ELD for a given spin system. Using different values of the β flip angle of the pulse sequence

$$\frac{\pi}{2} - t_1 - \beta - \tau_m - \beta - t_2 \quad (7)$$

the authors showed that it is possible to determine the topology of two connected frequencies by observing how

the intensity of the cross peak varies with β . Knowing the topology of the connections for nearly all the observed lines in the spectrum, the energy level subdiagram for an A_3B and an A_2BC spin system were constructed, even when some connections were determined incorrectly. For each different possible assignment (864 for the A_2BC , and 8 for the A_3B spin system), the spectral parameter set was refined according the Swalen–Reilly iterative method. The spectrum was calculated and the best assignment was chosen by comparing the calculated and experimental spectra.

A generalization of the method would require a library containing topologies of ELDs for spin systems of different symmetries. Improvements are needed to take into account the extensive degeneracy that can occur for larger spin systems. Such degeneracies can be due either to accidental overlaps of lines in crowded spectral regions or to the poor digital resolution of the two-dimensional spectra of liquid crystalline phases.

4.2 Spectral Simplification Based Approaches

As an alternative approach to the automated methods, experiments aimed at reducing the complexity of spectra can be planned. In this way spectral analysis will be simplified and the rate of success increased.

4.2.1 Spectral Simplification via Deuterium Decoupling

Selectively deuterated molecules give quite complex ^1H spectra (the anisole- d_3 spectrum in ZLI 1115 being a lucky exception), even if, at first glance, they look fairly simple. There are, in fact, a larger number of lines in such spectra, as deuterium has $I = 1$ while the larger linewidth, due to the ^2H quadrupolar relaxation, combined with the lower values of the D_{HD} couplings ($\gamma_{\text{H}}/\gamma_{\text{D}} \simeq 6$), causes widespread overlapping of transitions.

Spectral simplification can be obtained by performing $\{^2\text{H}\}-^1\text{H}$ decoupling experiments, and good results have been obtained with solenoid probes. Using short acquisition times ($<0.2\text{ s}$) when the decoupler is on, and a delay of typically 3 s to allow cooling to occur and to reduce thermal inhomogeneities, decoupled spectra from complex spin systems such the eight protons in 4-trideuteromethoxy-4'-cyanobiphenyl¹² have been recorded and successfully analyzed.

The procedure just described is the one usually followed when complex spectra are analyzed using this approach: ^1H spectra (with and without deuterium decoupling) of different selectively perdeuterated isotopomers are recorded under similar experimental conditions (solvent, temperature and concentration) and analyzed from the simpler to the more complex spin systems in order to obtain a good starting parameter set for the analysis of the spectrum of the fully protonated molecule. The full procedure requires much synthetic and spectral analysis work, but it is applicable whenever selective deuteration is possible and gives a very high success rate—its upper limits being an analyzable ^1H spectrum of the fully protonated species.

As an alternative to the high power decoupling technique, the sequence which refocuses heteronuclear coupling,

$$\left(\frac{\pi}{2}\right) - \tau_1 - (\pi) - \tau_1 - \text{Sample} \quad (8)$$

can be used:²³ τ_1 is increased at fixed intervals and the first point of each FID taken at the top of the echo is stored in a vector. The vector is Fourier transformed to give the decoupled, $\Delta\nu_i = 0$ spectrum. In fact the selective pulse sequence is such that at the top of the echo the magnetization does not depend on the heteronuclear couplings. The experiment takes a long time and has lower sensitivity than decoupling. In addition, artifacts due to pulse and phase imperfections have to be considered, but these can be significantly reduced in modern instrumentation. The spin echo experiment has the great advantage that all the heteronuclear couplings due to nuclei with different γ values are decoupled at once. If the antiecho is recorded, homonuclear couplings are refocused and the spectrum depends only on heteronuclear couplings (see *Spin Echo Spectroscopy of Liquid Samples*).

4.2.2 Spectral Simplification via Multiple Quantum Spectroscopy

This approach is discussed elsewhere (see *Multiple Quantum Spectroscopy in Liquid Crystalline Solvents*). Here it is sufficient to remember that for a given spin system composed

of N nonequivalent spins $\frac{1}{2}$, the maximum possible number of transitions of order p is

$$Z_p = \binom{2N}{N-p} \quad (9)$$

for $1 \leq p \leq N$.²⁴ It is clear that even a very complex spin system will give simple spectra when p is $N - 1$ or $N - 2$ and these spectra will contain the same information that can be obtained from the single quantum ordinary spectrum with

$$Z_p = \binom{2N}{N-1} \quad (10)$$

4.2.3 Double Quantum Two-Dimensional Correlated Experiments

In a series of very elegant papers, Pines et al. applied multiple quantum (MQ) spectroscopy to a class of compounds, the n -alkanes, whose proton spectra are too complex to analyze. The molecules chosen, from n -hexane²⁵ to n -decane,²⁶ were randomly perdeuterated in such a way to have a negligible population of isotopomers with more than three protons left, but with all the possible two- and three-protonated isotopomers having a nearly uniform population distribution. This is easily done via a catalytic exchange reaction for n -alkanes, but the required population distribution may not be reached in such a direct way for other molecules having functional groups. This limits the generalization of the method to other organic compounds. A two quantum filtered experiment reduces the complexity of the spectrum leaving only AB and A_2 (16 for n -hexane) spin systems. A four-step phase cycling keeps the total number of averaged FIDs for each t_1 (96 for 24 increments in τ ²⁵) acceptably low, to ensure a digital resolution of nearly 30 Hz per point. The phase cycling selects even quantum coherences: the sweep width is then kept small by the isotopomer population distribution because no four or higher coherences are possible. On the other hand, it is crucial that the double quantum coherence of all the AB spin systems is present. As the D_{ij} values cover a wide range, this can be achieved only by coadding FIDs obtained with different τ values; the data acquisition time will thus be lengthened significantly. To distinguish signals belonging to different spin systems, a two-dimensional correlation experiment can be performed. The two last steps are possible using the pulse sequence

$$\begin{aligned} &\left(\frac{\pi}{2}\right)_\phi - \tau - \left(\frac{\pi}{2}\right)_\phi - \frac{t_1}{2} - (\pi) - \frac{t_1}{2} - \left(\frac{\pi}{2}\right)_x \\ &- \frac{\tau_2}{2} - (\pi) - \frac{\tau_2}{2} - t_2 \end{aligned} \quad (11)$$

All the spectra were recorded with continuous deuterium decoupling,²⁷ which causes considerable heating and thermal inhomogeneities, despite air-flow temperature control. All the couplings (up to 20 for n -decane) were determined with an experimental error of about 25 Hz, the low accuracy being a consequence of the low digital resolution and thermal gradients.

4.2.4 Spectral Simplification via Scaling of Dipolar Couplings

As previously stated, one of the reasons for the complexity of anisotropic spectra is the non-first-order character of the

spectra. Another way to simplify the analysis of such spectra is to scale the direct couplings by some factor, thus leaving only a few couplings (the biggest) that are greater than the spectral linewidth. In this way first-order features will appear in the spectrum if the chemical shift differences are large enough, and the number of lines in the spectrum will be reduced. In principle, all these improvements could be achieved simply by changing the experimental conditions that decrease the solute order (temperature and/or solute concentration), but this is in practice unachievable because the S matrix changes discontinuously at the nematic–isotropic transition temperature T_{NI} .

Courtieu et al.²⁸ applied the variable angle technique (using a spinning angle of 51°), developed for NMR in solids, to scale dipolar couplings, thus reducing the ABC pattern in CF_2CFBr to a first-order, easily analyzable AMX spectrum. At lower angles, non-first-order features began to appear but, because the authors were able to register the spectra at lower spinning angles, the line patterns can be easily followed and the dipolar couplings calculated at a spinning angle of 0° (*Spinning Liquid Crystalline Samples*).

Scaling of dipolar couplings can be achieved by using a suitable pulse sequence (PARDES) derived from the well-known WAHUA and MREV sequences,²⁹ as described by Frydman et al.³⁰ The reduction in the splitting of the doublet due to CH_2Cl_2 dissolved in a nematic mesophase was followed by varying the parameters in the sequence.

1 INTRODUCTION

The introduction of the Hartmann–Hahn¹ technique of cross polarization into solid state nuclear magnetic resonance spectroscopy, particularly when combined with multiple pulse methods² to remove homo- and heteronuclear, dipolar broadening, was a significant addition to the methods available for the study of solid compounds by NMR. When cross polarization and proton decoupling were incorporated into the magic angle spinning technique,³ there was produced a significant enlargement of the repertoire of sensitive NMR spectrometric procedures available for obtaining high-resolution spectra of solid state compounds and materials.⁴ This important new spectroscopic method became known as cross polarization magic angle spinning (CP MAS) NMR. When the ¹³C spectra of compounds containing nitrogen were studied by CP MAS some lines appeared as broadened asymmetric doublets. It was soon realized that this characteristic lineshape resulted from the ¹⁴N nuclear quadrupole moment interfering with the ability of the magic angle spinning to average out the ¹³C–¹⁴N dipolar interactions. This interpretation was based on earlier observations of the ¹³C lineshapes of carbon nuclei bonded to nitrogen in the NMR of single crystals. We shall now briefly describe the main features of such high-resolution NMR spectra of single crystals to provide a suitable background for understanding the theoretical interpretation of the asymmetrical ¹³C–¹⁴N lineshapes in CP MAS spectra.

1.1 Single Crystal NMR Spectra

Within a short time after their introduction, the new NMR spectroscopic techniques were applied to obtain ¹³C chemical shielding data on a wide range of organic compounds. It was soon found in compounds containing a nitrogen nucleus adjacent to the carbon nucleus being studied that splittings

from ¹³C–¹⁴N dipolar couplings were observed. Griffin et al.⁵ found that the NMR spectrum of a single crystal of glycine at a certain orientation with respect to the magnetic field exhibited three lines from the methylene carbons split by adjacent ¹⁴N nuclei. In measurements of the ¹³C chemical shielding tensor in the metal complex K₂Pt(CN)₄Br_{0.3}·3H₂O, Stoll et al.⁶ observed large effects clearly shown to be caused by ¹⁴N quadrupolar interactions. In that compound, the electric quadrupolar interactions are of comparable size to the ¹³C–¹⁴N dipolar interaction; consequently, mixing with the pure Zeeman eigenfunctions occurs. These required eigenfunctions were obtained by the application of first-order perturbation theory and subsequent diagonalization of the combined Zeeman-quadrupole Hamiltonian. Stoll et al. assumed an axially symmetric electric field gradient tensor with its symmetry axis along the C–N bond. Good quantitative agreement was found between the theoretical and experimental spectral lineshapes for all the angular variations studied.

Because amino acids are of great biological importance, the observations of ¹³C–¹⁴N dipolar–quadrupolar interactions clearly meant that single crystal NMR spectra of amino acids would soon be investigated. Thus simultaneously there were reported such detailed studies of alanine⁷ and glycine.⁸ Though these two detailed single crystal studies cover similar ground, we shall give details about the more complete studies of alanine and use some of the theoretical ideas later in our discussion of the effects of ¹⁴N quadrupolar interactions causing asymmetry in certain magic angle spectral lineshapes of compounds with C–N bonds.

The proton-enhanced proton-decoupled ¹³C NMR spectra of a single crystal of L-alanine were studied by Naito et al.⁷ The C- α line showed a triplet pattern arising from dipolar coupling with the ¹⁴N (*S* = 1) nuclei (Figure 1). These splittings were asymmetric, especially in the α -axis orientation. The dipolar interactions in the presence of the ¹⁴N quadrupolar interaction were calculated by applying ideas first employed by VanderHart et al.⁹ to provide a theoretical analysis of the static proton resonance spectra of polycrystalline HMn(CO)₅ and HCo(CO)₄. The appropriate Hamiltonian for the case where the quadrupole asymmetry parameter η is zero is written in the following form for later convenience:

$$\mathcal{H} = -\gamma_N \hbar B_0 S_z + \frac{\chi \hbar}{4S(2S-1)} [3S_z^2 \cos^2 \theta + 3S_x^2 \sin^2 \theta + 3(S_z S_x + S_x S_z) \sin \theta \cos \theta - S^2] \quad (1)$$

where the quadrupolar coupling constant is $\chi = e^2 q Q / h$. This Hamiltonian was used to determine the required eigenfunctions of the ¹⁴N nucleus, and these in turn employed to calculate the eigenfunctions of the ¹³C–¹⁴N dipolar interaction as a function of θ , the angle between the direction of the external magnetic field and the symmetry axis of the electric field gradient tensor, i.e., the C- θ –N bond direction. It was thus possible to calculate the three ¹³C resonances predicted (and observed experimentally for the C- α nucleus) which correspond to the nitrogen Zeeman states $|+1\rangle$, $|0\rangle$, and $|-1\rangle$, respectively. When the sign of the quadrupole coupling constant was assumed to be positive, good agreement was found between the calculated and experimental data for all the angles studied. The experimental results thus give the sign of the quadrupole coupling constant.

2 MAGIC ANGLE SPINNING

As is well known, MAS tends to average out anisotropic interactions to their corresponding isotropic values when they are very weak as compared with their Zeeman interactions. Theoretical consideration of the effect of the ^{14}N quadrupolar interaction on the ^{13}C MAS spectra based on the above ideas, show that for ^{13}C nuclei bonded to ^{14}N an asymmetric doublet pattern is expected. Lippmaa et al.¹⁰ reported that a high-resolution rotational-synchronized proton-enhanced magic angle spinning ^{13}C NMR spectrum of the polycrystalline solid of the one-dimensional compound tetrathiofulvalene-tetracyanoquinodimethane (TTF-TCNQ) exhibited a three-line spectrum, one line of which consisted of an asymmetric doublet which they attributed to the C-N group. The splitting was found to be field-dependent and identified as arising from dipole-dipole interaction with the ^{14}N nuclei having a quadrupole interaction of comparable magnitude to their Zeeman interaction. This was the first observation of an asymmetric lineshape in a ^{13}C magic angle spinning NMR spectrum of a compound containing a ^{13}C - ^{14}N bond.

3 EFFECTS OF AN AXIALLY SYMMETRIC ELECTRIC FIELD GRADIENT

The influence of spinning on the solid state NMR spectrum of a molecular system consisting of spin pairs in which one of the two spins has a quadrupole moment was first treated theoretically by Kundla and Alla.¹¹ The quadrupolar interaction fixes the spin moment at a definite orientation in the principal axis system (PAS) of the molecule. Rotation of the sample causes a rotational synchronized movement of the spin moment which does not permit the complete averaging of the dipole-dipole interaction between the spin- $\frac{1}{2}$ nucleus I and the quadrupole nucleus $S = 1$. The degree of the averaging depends on the ratio of the quadrupolar and Zeeman energies of the S nucleus.

The Hamiltonian may be written as

$$\mathcal{H} = \mathcal{H}_Z^I + \mathcal{H}^S + \mathcal{H}_D^{IS} \quad (2)$$

Here $\hat{\mathcal{H}}_Z^I$ is the Zeeman term of the I nucleus, $\mathcal{H}^S$ is the quadrupolar Hamiltonian, and $\mathcal{H}_D^{IS}$ the dipolar interaction

Hamiltonian between the I and S spins. It is assumed that $\mathcal{H}_D^{IS}$ is small so that first-order perturbation theory may be applied to calculate the resonance frequencies of the I -spin spectral lines. Because of the rotation of the sample at frequency ω_r , the eigenfunctions and eigenvalues of the unperturbed system become time-dependent. These were calculated for the case where the quadrupole coupling is symmetric. The energy levels were expressed in terms of parameters such as $k = \omega_Q/\omega_Z^S$; θ , the angle between the rotation axis and the magnetic field; the Euler angles α , β , and γ of the sample-fixed coordinate system, in which the α axis coincided with the rotational axis; and the PAS. When $\theta = 0$, the eigenvalue equations became the same as those giving the dependences of the spectral lines on the orientation of the nonrotating single crystal as described by Stoll et al.⁶ To obtain the lineshapes and resonances of the polycrystalline sample at high spinning speeds, the average positions, $\overline{\Delta_n^D}$, were obtained by averaging over all orientations represented by the angle β . Numerical calculations for the magic angle case showed that the line splittings and total widths depend strongly on the relative strengths of the Zeeman and quadrupolar interactions. Moreover, it was shown that in a strong magnetic field, the I -spin spectrum is an asymmetric doublet, one of the lines being the sum of two components, the full width of the single line being twice as large as that of the composite line. The splitting increased with increasing k leading to a regular triplet. The isotropic spin-spin interaction between the I and S nuclei was predicted to shift the I -spin spectral lines, the effect decreasing with increasing values of k .

Apparently unaware of the above work of the Estonian scientists, several groups reported CP MAS spectra of polycrystalline organic compounds containing C-N bonds such as amino acids, peptides, and proteins in which significant differences were observed between the solid state spectra and those in solution.^{12,13} Most of the resonances from carbons bonded to nitrogens were split into broadened doublets, and some of the resonances from more distant carbons were also affected.

A classical and much studied example is the CP MAS spectrum of polycrystalline alanine.¹⁴ The observed splittings of the asymmetric doublet of the C- α resonance was 45 Hz with a 200 MHz magnet and ~ 100 Hz when measured at 90 MHz. The spectra can be fully interpreted and quantitatively explained by the following theoretical treatment.¹⁴ First, the ^{14}N quadrupolar interaction is of comparable magnitude to the Zeeman interaction, so the ^{14}N spin eigenfunctions must be determined by diagonalizing the nitrogen Zeeman quadrupole Hamiltonian, and those eigenfunctions used in the calculation of the ^{13}C - ^{14}N dipolar interactions. At the outset it should be understood that in this problem it is important to be mindful of the timescale of the magic angle spinning. In the experiments described by Naito et al.¹⁴ the spinning frequency was 4.5 kHz, which is small compared with the ^{14}N quadrupolar interaction in L-alanine for which $\chi = 1.205$ MHz; the adiabatic approximation can therefore be employed to determine the nitrogen spin functions at time t from the following equation

$$\mathcal{H}_{ZQ}\psi_N(t) = E(t)\psi_N(t) \quad (3)$$

Here, $\mathcal{H}_{ZQ}(t)$ is the Zeeman quadrupole Hamiltonian of the nitrogen nuclei at time t . For the amino nitrogen in amino

acids and the cyano nitrogen in nitriles, one may assume with a high degree of accuracy that the electric field gradient tensor is axially symmetric, i.e., $\eta = 0$. Thus for the MAS spectrum of L-alanine we can write the Zeeman quadrupole Hamiltonian as

$$\begin{aligned} \mathcal{H}_{ZQ}(t) = & -\gamma_N \hbar S_z B_0 + \frac{\chi \hbar}{4S(2S-1)} [3S_z^2 \cos^2 \theta(t) \\ & + 3S_x^2 \sin^2 \theta(t) + 3(S_z S_x + S_x S_z) \sin \theta(t) \\ & \times \cos \theta(t) - S^2] \end{aligned} \quad (4)$$

Here, $\theta(t)$ is the periodic value of the angle between the field direction $\mathbf{B}_0$ and the internuclear vector $\mathbf{r}_{CN}$. Under MAS, when a rigid array of nuclei is rotated with an angular velocity ω_r about an axis inclined at an angle β to the direction of the external magnetic field $\mathbf{B}_0$, and at an angle β' to $\mathbf{r}_{CN}$, we may write that $\theta(t)$ can vary as follows:

$$\cos \theta(t) = \cos \beta \cos \beta' + \sin \beta \sin \beta' \cos(\omega t + \psi) \quad (5)$$

where ψ is the azimuthal angle of $\mathbf{r}_{CN}$ at time $t = 0$.

In this case the ^{13}C – ^{14}N dipolar interaction is very small compared with the Zeeman interaction, so first-order perturbation theory can be used to calculate the ^{13}C – ^{14}N dipolar interaction at time t . The dipolar splitting of the ^{13}C resonance resulting from that calculation using the Hamiltonian $\mathcal{H}_{ZQ}$ represented by equation (3) yields

$$\begin{aligned} \Delta E_i(t) = & -\gamma_C \gamma_N \hbar^2 / r_{CN}^3 \{ [a_i(t)^2 - c_i(t)^2] [1 - 3 \cos^2 \theta(t)] \\ & - (9/2)^{1/2} [a_i(t) + c_i(t)] b_i(t) \sin 2\theta(t) \} \end{aligned} \quad (6)$$

Here, $a_i(t)$, $b_i(t)$, and $c_i(t)$ ($i = 1, 2$, and 3) are the coefficients at time t of the Zeeman quantized spin functions of the nitrogen nuclei, namely, $|1\rangle$, $|0\rangle$, and $|-1\rangle$, respectively. In L-alanine the ^{13}C – ^{14}N dipolar interaction, 0.6636 kHz, is small compared with the spinning frequency 4.5 kHz, so in such cases the $\Delta E_i(t)$ have to be averaged from $t = 0$ to $t = \infty$ to obtain the ^{13}C – ^{14}N dipolar energy of the spinning sample. The values of $\Delta E_i(t)$ were calculated for each 5° of $\omega t + \psi$ in the range 0° to 360° with constant β' , and these values were then averaged to yield $\overline{\Delta E_{i\beta'}(t)}$. The theoretical lineshapes for polycrystalline samples rotating at the magic angle $\beta = 54.7^\circ$ are obtained by calculating the numerical values of $\overline{\Delta E_{i\beta'}(t)}$ when β' is varied in steps of 2° in the interval 0° to 90° , each $\overline{\Delta E_{i\beta'}(t)}$ being weighted by its probability $\sin \beta'$. Finally, convoluting the theoretical lineshapes with a Gaussian function gave the actual lineshape. The linewidth of the Gaussian function is an adjustable parameter which takes into account any instrumental line broadening, such as effects arising from improper decoupling setting, any slight misalignment of the magic angle, and any magnetic field inhomogeneities, etc.

As shown in Figure 1, the calculated and experimental spectra agreed well. Clearly the calculated lineshape is an asymmetric doublet with a splitting of 48 Hz for a ^{13}C resonance frequency of 50.3 MHz and 108 Hz for a resonance frequency of 22.6 MHz, both values in good agreement with experimental observations.^{12,14} This field-dependence of the asymmetric doublet splitting arises because a weak field causes a relative increase in the contributions from the off-diagonal elements of the matrix representation of the Hamiltonian

$\hat{\mathcal{H}}_{ZQ}(t)$. Noteworthy also was the finding that when the sign of the term $\chi \hbar$ in the lineshape calculation was chosen as negative, the shape was reversed, i.e., the intensity of the high-frequency (low-field) peak was now stronger than the other one. This observation thus presents a means of determining the sign of the quadrupole coupling constant of ^{14}N bonded to ^{13}C by lineshape analysis of the CP MAS ^{13}C NMR spectra.

When the spectrum of cyanoacetamide was studied the same theoretical treatment was applicable because here also the ^{13}C – ^{14}N dipolar interaction, 1.46 kHz, was smaller than the rotor spinning frequency. The lineshape exhibited a reversal of the intensities of the doublet components. When the value of $\chi \hbar$ was taken to be negative, the simulated lineshape was in good agreement with that observed experimentally. The splitting of the asymmetric doublet for the nitrile was 338 Hz in the simulated spectrum, in good agreement with the experimentally measured splittings of 305 Hz to 356 Hz for different cyano compounds.

The above theoretical treatment and the simulated MAS lineshapes were based on the important assumption that the rotor spinning speed was very small in comparison with the size of the quadrupole interaction of the ^{14}N nucleus in the molecule. It was, however, shown that if the spinning speeds were as large as the ^{14}N quadrupolar interaction (i.e., in the MHz range), which seems highly unlikely, the lineshape predicted is quite different from those obtained at low spinning frequencies. For the extremely high spinning frequency case, a truncated Zeeman quadrupole Hamiltonian $\hat{\mathcal{H}}_{ZQ}(t)$ (the time-dependent part is truncated) can be used for the MAS lineshape calculation. Using the same parameters as employed in the simulation of the spectra of nitrile compounds with a value of $\chi = 3.87$ MHz and 24 Hz for the halfwidth of the Gaussian broadening function, it was found that the predicted splitting is less than one-third of the slow-spinning case, giving a broad powder pattern as the expected lineshape.

Contemporaneously with the above work, Zumbulyadis et al.¹⁵ presented an extensive analysis of the influence of quadrupole nuclei on the magic angle spinning spectra of spin- $\frac{1}{2}$ nuclei. Here also, as above, the treatment was restricted to the case with an axially symmetric quadrupolar tensor. The formal theory described was similar to that described above; it also made use of the adiabatic approximation, in which a time-dependent wavefunction is approximated by an eigenfunction of the instantaneous Hamiltonian multiplied by a time-dependent phase factor. Theoretical powder patterns were calculated for a range of values of parameters typical of ^{13}C coupled to ^{14}N , the results being given as a function of ratio of the spin-1 Zeeman frequency Z to the quadrupole coupling constant χ . Each spectrum consisted of double-peaked bands with an intensity ratio of 1:2; the ratio of the S -spin Zeeman to the quadrupolar interaction (Z/χ) determined the widths of the bands and the splittings between them. This was also implicit in the theories of Naito et al.^{14,16} as was the finding that both the widths and splittings of the bands decrease at higher magnetic fields where the quadrupolar interaction induces less mixing of the S -spin Zeeman eigenstates. It was also shown that the appearance of the bands depended critically on the mutual orientations of the unique principal axes of the dipolar and quadrupolar interaction tensors, the doublet splitting going through a minimum when the two principal axes were oriented at the magic angle *with respect to each other*.

4 ¹⁴N EFFECTS OF AN ASYMMETRIC ELECTRIC FIELD GRADIENT

Though the above theoretical treatments^{14,15} were successful in providing an interpretation of the CP MAS ¹³C spectra of a number of nitrogen-containing compounds and, in particular, explaining the asymmetric lineshapes associated with C–N bonds, the restriction to cases with symmetric ¹⁴N quadrupolar tensors was limiting. When the quadrupole coupling parameter $\eta \neq 0$, the C–N bond direction may not be parallel to the principal axis of the quadrupolar tensor. In this situation the off-diagonal elements in the matrix representation of the Hamiltonian $\mathcal{H}_{ZQ}$ will contain η , and hence a large value of the quadrupolar asymmetry parameter will be quite effective in determining the resulting MAS lineshape.

To extend the theory to include the ¹³C CP MAS spectra of important organic molecules such as nitroanilines, and biomolecules like imidazoles, polypeptides, and proteins in which the influence of asymmetry of the ¹⁴N quadrupole coupling tensor may play an important role in determining the lineshapes of the spectra, it was necessary to extend the theoretical formulation though the basic ideas were still sufficient to permit the required extension to encompass a wider range of molecular environments.¹⁶

The adiabatic approximation represented by equation (2) is still used but the Zeeman quadrupole Hamiltonian for ¹⁴N must be modified to reflect the asymmetry of η , the nitrogen asymmetry parameter. The Hamiltonian is now written as

$$\mathcal{H}_{ZQ}(t) = -\gamma_N \hbar B_0 S_z' + \frac{eQq_{zz}}{4S(2S-1)} \times \{(3S_z'^2(t) - S^2) + \eta[S_x'^2(t) - S_y'^2(t)]\} \quad (7)$$

where $\eta = (q_{xx} - q_{yy})/q_{zz}$; eq_{ii} are the principal values of the electric field gradient tensor at the ¹⁴N nucleus in the compound. They obey the convention that $|q_{zz}| \geq |q_{yy}| \geq |q_{xx}|$. The quantity e^2Qq_{ii} ($i = x, y, z$) is one of the principal values of the quadrupole coupling tensor and e^2Qq_{zz} is the quadrupole coupling constant. In this case there are two different coordinate systems to be considered. The Zeeman coordinate system is specified by (x', y', z') , and the principal axis system coordinates of the ¹⁴N electric field gradient tensor of the compound by (x, y, z) . The Euler angles of the spinner rotation axes (x^R, y^R, z^R) are written as β' , θ , and ψ . The magic angle spinning axis, z^R , is inclined at an angle β' with the z axis, and at the magic angle β to the static magnetic field (Z'). The angle ψ is time-dependent and given by $\psi = \omega_r t + \psi_0$, where ψ_0 is the initial angle when $t = 0$ and ω_r is the angular velocity of spinning. Transformations of the coordinate systems (see Figure 2) give the ¹⁴N Zeeman quadrupole Hamiltonian in the Zeeman coordinate system, and the resulting eigenstates are used to calculate the ¹³C–¹⁴N dipolar energy. Since, in general, the internuclear vector r_{CN} is not collinear with the z axis of the electric field gradient tensor, its direction is defined by the polar angles (θ, ψ) in the principal axis system of the electric field gradient tensor. First order perturbation theory can again be used to calculate the ¹³C–¹⁴N dipolar energy of the ¹³C resonance of a certain

Figure 2 Diagrammatic representation of the coordinate transformations required to calculate the ¹³C lineshapes when the quadrupolar parameter η is asymmetric. They can be summarized as follows:

$$\begin{array}{ccccc} x, y, z & & x^R, y^R, z^R & & x', y', z' \\ \text{Principal} & \xrightarrow{(\beta', \phi, \psi)} & \text{Rotating} & \xrightarrow{(\beta, 0, 0)} & \text{Zeeman} \\ \text{axis system} & & \text{axis system} & & \text{axis system} \end{array}$$

molecular orientation at time t and is given by

$$\Delta E_{i\beta'\Phi}(t) = \langle \beta | \psi_N(t) | \mathcal{H}_D(t) | \beta \rangle \psi_N(t) - \langle \alpha | \psi_N(t) | \mathcal{H}_D(t) | \alpha \rangle \psi_N(t) \quad (8)$$

Here, $|\alpha\rangle$ and $|\beta\rangle$ are the ¹³C Zeeman spin functions. As before, the ¹³C–¹⁴N dipolar interaction is smaller than the spinning frequency, so $\Delta E_{i\beta'\Phi}(t)$ must be averaged over one rotor cycle, i.e., from $t = 0$ to $t = \infty$, to give the ¹³C–¹⁴N dipolar energy in the spinning sample, namely

$$\overline{\Delta E_{i\beta'\Phi}(t)} = (1/2\pi) \int_0^{2\pi} \Delta E_{i\beta'\Phi}(\psi) d\psi \quad (9)$$

The values of $\overline{\Delta E_{i\beta'\Phi}(t)}$ were calculated numerically for small increments of the appropriate angles and the resulting values averaged. The resulting theoretical averaged line positions for the spinning sample were weighted by their probability, $\sin \beta'$, and then convoluted with a suitable lineshape function to yield the actual lineshape.

One of the first compounds chosen to test the above theory for calculating the MAS lineshapes of molecules containing ¹⁴N nuclei with nonasymmetric quadrupolar tensors, i.e., with $\eta \neq 0$, was polycrystalline 2,6-dimethyl-3-nitroaniline. This molecule has two different types of ¹⁴N nuclei. The ¹³C MAS NMR spectrum showed that the resonances for both the nitro and amino carbon nuclei exhibited asymmetric doublet patterns (Figure 3). The high-frequency line in the nitro doublet was more intense than the other component, whereas the reverse was the case for the amino peak. Clearly the differences in the lineshapes arose from the different signs, orientations, and magnitudes of the respective electric field gradient tensors for the two ¹⁴N nuclei. Calculations of the theoretical lineshapes by the method outlined above using the appropriate molecular parameters and a reasonable assignment for the orientation of the ¹⁴N electric field gradient tensor based on that of *p*-nitrotoluene yielded lineshapes similar to those observed

Figure 3 Lineshape of the resonance of the carbon nucleus adjacent to the NO₂ group in the ¹³C CP MAS spectrum of 2,6-dimethyl-3-nitroaniline. Computer-simulated spectrum calculated with a quadrupolar asymmetry parameter $\eta = 0.408$ and (a) the ¹⁴N quadrupolar coupling constant $e^2Qq_{zz}/h = -1.340$ MHz; (b) the quadrupolar coupling assumed to be positive. (Reproduced by permission of Academic Press from Naito et al.¹⁶)

experimentally. With the value of χ being 1.340 MHz and $\eta = 0.408$ for ¹⁴N of the -NO₂ group, good agreement was found with the experimental lineshape only when the sign of the quadrupole coupling constant was taken as negative. The simulation of the lineshape of the amino peak required more insight. Values for χ , η , and $\gamma_C\gamma_N\hbar/(2\pi r_{CN}^3)$, based on literature information, were chosen to be 3.977 MHz, 0.263, and 0.8466 kHz, respectively. In the case where the z axis of the quadrupole coupling constant was chosen to lie normal to the plane of the NH₂ group and the y axis assumed to be tilted 40° from the C-N bond direction, with the sign of the quadrupole coupling constant negative the resulting simulated lineshape was in excellent agreement with that observed experimentally. Also, the calculated value for the doublet splitting was 110 Hz, in good agreement with the observed value of 102 Hz.

It proved more difficult to provide an unambiguous interpretation of the lineshapes of the ¹³C CP MAS NMR spectrum of polycrystalline glycylglycine and glycyl-L-alanine. Here again the orientation of the principal axes of the ¹⁴N quadrupole coupling tensor was unknown. Proceeding as before, the calculated lineshapes for the case where the z axis was assumed to lie along the direction of the N-H bond led to a narrow singlet pattern not in agreement with the experimental spectrum. When the z axis was chosen to be normal to the C-N-C plane and the y axis along the N-H bond, the simulated lineshapes again did not agree with the observed lineshape. Several possible orientations of the axes were tried, but only when the z axis of the quadrupole tensor of the amino nitrogen was assumed to lie along the C-N bond direction and the sign of the quadrupole coupling constant taken as positive, together with acceptable values of the other constants, was a satisfactory lineshape simulation obtained. Moreover, the calculated doublet splitting for the C- α carbon in glycylglycine was 49 Hz, which was in good agreement with the experimental value of 41 Hz.

Given the satisfactory simulations of the observed lineshapes from the theory for amino acids and polypeptides, attention was then turned to a more sophisticated molecule of biological interest, namely, trimethylimidazole. This molecule

has two different types of nitrogen nuclei. The quadrupole coupling constants and asymmetry constants of the two nitrogen nuclei are for N-1, $\chi = 1.424$ MHz and $\eta = 0.980$, and for N-2 $\chi = 3.267$ MHz and $\eta = 0.129$. The large difference in the two quadrupolar tensors for the two nitrogen nuclei is obviously mainly the cause of the notable difference between the lineshapes observed for the C-4 and C-5 carbon atoms in the CP MAS spectrum of ¹³C in this compound. Nevertheless, it was only possibly to simulate the experimental lineshapes successfully after a judicious choice of the orientations with respect to the molecular axes of the respective quadrupolar tensor axes.

Furthermore, this work clearly showed that in nitrogen-containing organic compounds, if the correct quadrupole coupling tensor and the relative orientations of the principal axes with respect to the molecular axes are known for a particular nitrogen nucleus, it is possible to calculate the theoretical lineshape for the carbon nucleus bonded to the nitrogen. That the sign of the quadrupole coupling constant for the nitro and amino nitrogen atom in organic compounds differed was new. Since each group containing a nitrogen atom has a characteristic quadrupole coupling tensor, it follows that the ¹³C resonances in the CP MAS NMR spectra of the carbon atoms in such groups, e.g., -NO₂, -NH₂, $\equiv$ N, -NH₃⁺, and -CN, all exhibit characteristic lineshapes. This information is obviously of considerable practical importance for the assignment of the solid state ¹³C CP NMR spectra of organic compounds, particularly those of biological importance and heterocyclic compounds, pharmaceuticals, dyestuffs, etc.

Another approach to calculating the lineshapes of the ¹³C MAS spectra of nitrogen-containing organic compounds was put forward by Hexem et al.¹⁷ This was based on writing the Hamiltonian of the spin system in terms of irreducible spherical tensor operators, namely

$$\mathcal{H} = \sum_{\lambda} \sum_l \sum_{m=-l}^l (-1)^m R_{l-m}^{\lambda} T_{lm}^{\lambda} \quad (10)$$

In this equation, λ represents the type of interaction, including the Zeeman interactions for the carbon, Z_C , and nitrogen spins, Z_N ; the quadrupole interaction of the nitrogen spin, Q ; D , the ¹³C-¹⁴N dipolar interaction; and CS , the chemical shielding of the carbon spins. The quantity J , the indirect spin-spin interaction, is ignored because it was assumed to be negligible. The rotational properties of the irreducible spherical tensors were used to obtain the Hamiltonian in a more convenient form. The time-dependence of the resulting Hamiltonian was removed by applying average Hamiltonian theory. The part of the average Hamiltonian representing the dominant interactions of the carbon atoms and which commutes with the appropriate Zeeman Hamiltonian can be written as

$$\begin{aligned} \mathcal{H}^C(\phi) = & C^Z \rho_{00}^Z T_{00}^Z + C^{CS} \rho_{00}^{CS} T_{00}^{CS} \\ & + \sum_{m=-2}^2 C^D (-1)^m R_2^D - (\phi) T^D 3_{2m} \end{aligned} \quad (11)$$

where $C^Z = \gamma_C \hbar$, $C^{CS} = \gamma_C$, $\rho_{00}^{CS} = \sigma_{iso}$, $T_{00}^Z = B_{00} I_z$, $C^D = -2\gamma_C\gamma_N\hbar^2$, and σ_{iso} is the isotropic chemical shift. Making use of Wigner rotation matrices, one set of Euler angles transforms the principal axis system of the dipolar interaction

to the principal axis system of the electric field tensor, while the angles $(0, \theta_M, \psi)$ transforms further the spatial components to the axis system of the spinning rotor. In this last transformation, θ_M is the magic angle (54.7°) and ψ is the azimuthal angle of rotation about the rotor axis.

The shifts in the energy levels of ^{13}C were calculated using zero-order average Hamiltonian theory, which is equivalent to first-order perturbation theory, this procedure being possible because the small size of the dipolar coupling means that it can be treated as a perturbation. Because of the relative orders of magnitude of the ^{14}N quadrupole coupling constant and the lower achievable spinning rates, one cannot use zero-order average Hamiltonian theory to average $\hat{\mathcal{H}}_{\text{CN}}^{\text{D}}$, the heteronuclear Hamiltonian over one rotational period. The ^{14}N matrix was diagonalized and the induced carbon shifts calculated. The carbon shifts were calculated for a sufficient number of points as described in the earlier theoretical treatments. These dipolar shifts were averaged over one rotation period $\overline{\omega_n^{\text{C}}}$ by numerical integration over the azimuthal angle of rotation, ϕ . This is equivalent to assuming the adiabatic approximation for calculating the change of the nitrogen states over the rotational period described in detail earlier by Naito et al.^{14,16} and by Zumbulyadis et al.¹⁵

As a preliminary test of theory, and to compare the results from diagonalizing the nitrogen Hamiltonian matrix with those obtained by using first-order perturbation theory to obtain the coefficients in the eigenfunction $\Phi_n^{\text{N}}(\phi)$ representing a linear combination of the Zeeman spin states, Hexem et al.¹⁷ calculated the expected powder ^{13}C spectrum for a C–N bond. Typical values of the parameters were used and the quadrupole coupling tensor was assumed to be axially symmetric with $\eta = 0$. When these theoretical predictions for the lineshapes were compared with the experimental observations for polycrystalline alanine, it was clear that the spectra lacked the resolution to show the fine structure predicted by the powder pattern. The calculated spectrum obtained using a value of 0.26 for the quadrupole asymmetry parameter, η , and taking its sign as positive was in good agreement with the experimental spectrum, in general accord with the findings of Naito et al.¹⁶

Explaining the ^{13}C lineshape of the α -carbon in *N*-acetylvaline was more challenging. In this case $\eta = 0.31$ and in the case of the polypeptide bond study of Naito et al.¹⁶ it was necessary to consider carefully the relative orientations of the principal axes of the electric field gradient tensor with respect to the molecular axes. Consideration of several orientations soon yielded a set of parameters which produced good agreement between the computer simulated lineshape and that observed experimentally.

The extensive studies of Hexem et al.¹⁷ and Naito et al.¹⁶ showed clearly that comparing the experimental and computer-calculated spectra provides a ready method for obtaining information concerning the relative orientations of the dipolar and electric field gradient tensors from the manifestations of the influences of those parameters on the ^{13}C NMR lineshapes. Moreover, such studies also enable the sign of the asymmetry parameter of the ^{14}N nucleus bonded to the carbon to be established. Also, as is clearly apparent from the theoretical treatments outlined earlier in this article, the extent of the splitting between the doublet peaks characteristic of the ^{13}C resonance of a C–N bond depends on the magnitude and the asymmetry parameter of the ^{14}N quadrupole tensor, the

internuclear distance, the strength of the applied magnetic field, and the orientation of the internuclear vector r_{CN} in the principal axis system of the electric field gradient tensor.¹⁸

Kundla and Alla¹¹ had earlier shown that the line splittings and total widths depended on the relative strengths of the Zeeman and quadrupolar interactions. The magnitude of the splitting is directly dependent on the dipolar interaction and the asymmetry parameter, which is different for differing values of the Euler angles defining its spatial orientation, with the Zeeman frequency of the ^{14}N nucleus being Z_{N} , the dipolar coupling $D = \gamma_{\text{C}}\gamma_{\text{N}}\hbar/4\pi^2 r_{\text{CN}}^3$, and the polar and azimuthal angles as β^{D} and α^{D} , the doublet splitting S is given by:

$$S = \frac{9}{20}(D\chi/Z_{\text{N}})(3\cos^2\beta^{\text{D}} - 1 + \eta\sin^2\beta^{\text{D}}\cos 2\alpha^{\text{D}}) \quad (12)$$

which is in terms of all the geometric ($r, \alpha^{\text{D}}, \beta^{\text{D}}$) and energy variables (χ, Z_{N}, η) up to first order in (χ/Z_{N}) . As a test of equation (13) the values of the splitting S predicted by that equation were plotted against the experimentally observed splittings for more than 20 compounds containing different types of C–N bonds.¹⁹ An excellent linear relationship was found which may, at first sight, seem surprising because of the wide range of different molecular species involved.

5 INFLUENCE OF J COUPLING

In the Hamiltonians used in all the theoretical treatments described, the term $\mathcal{H}_J$ representing the indirect J coupling was ignored. This was because the value of J_{iso} was expected to be so small that it would have little, or no effect, on the CP MAS lineshapes of ^{13}C – ^{14}N -containing compounds. The excellent agreements found between the experimental and theoretical lineshapes shows that this was usually an easily justifiable assumption. The inclusion of J coupling leads to the introduction of the term:²⁰

$$[-(\Delta J/3)(3\cos^2\beta^J - 1 + \eta\sin^2\beta^J\cos 2\alpha^J)] \quad (13)$$

where β^J and α^J give the orientation of the unique z axis of the $\mathbf{J}$ tensor in the PAS of the quadrupole tensor. To illustrate the effect of the J coupling, Figure 4 shows how the normal two-peak powder spectrum becomes a three-peak spectrum for the case of ^{14}N . The theoretical spectra were calculated from the computer program of Naito et al.,^{14,16} modified to include the term $\mathcal{H}_J$ in the Hamiltonian. The introduction of the indirect spin–spin coupling results in a splitting of the $m_{14\text{N}} = -1$ and $+1$ levels, while the $m_{14\text{N}} = 0$ peak is unaffected. In the calculations, the ^{14}N electric field gradient tensor was assumed to be axially symmetric with the largest principal component parallel to the ^{13}C – ^{14}N dipolar vector. A similar procedure was employed by Eichele and Wasylishen,²¹ though they used a different computer program based on the perturbation method to interpret and simulate the spectrum demonstrating the first observation of the indirect spin–spin coupling $^1J(^{14}\text{N}, ^{13}\text{C})$ effect which they discovered in the ^{13}C CP MAS NMR spectrum of $[(n\text{-C}_3\text{H}_7)_4\text{N}][\text{Cd}(\text{SCN})_3]$. Because of the excellent agreement found between the simulated and the experimental spectra they estimated the value of $^1J(^{14}\text{N}, ^{13}\text{C}) = 11 \pm 3$ Hz.

Figure 4 Diagrammatic representation of the effect of including the term $\mathcal{H}_J$ in the Hamiltonian before calculating the lineshape

6 OTHER SPIN- $\frac{1}{2}$ NUCLEI BONDED TO ^{14}N : ^1H CRAMPS

Protons are ubiquitous in nature and bond to many different types of nuclei. Of these the bonding to ^{14}N is important because N–H bonds are fundamental in the molecular composition of amino acids, polypeptides, and proteins. Unfortunately, the ^1H CP MAS spectra of such compounds were generally found to be lacking in structure because of the dipolar broadening caused by homonuclear interactions and magnetic shielding anisotropies. The introduction of the technique of combining sample rotation and multiple pulse NMR spectroscopy, the so-called CRAMPS procedure pioneered by Gerstein et al.,²² was a major innovative addition to the CP MAS methodology which considerably enlarged its range of applications, making it possible to obtain high-resolution proton spectra of hydrogen-containing solids many of which are of great industrial importance. When applied to solid amino acids the CRAMPS technique yielded proton CP MAS spectra in which there were identified²³ asymmetric peaks clearly arising from the ^1H – ^{14}N dipolar interaction and the ^{14}N quadrupole interaction not being averaged out, as earlier described for the analogous ^{13}C – ^{14}N case. The resolution of the characteristic asymmetric lineshapes varied with the type of multiple pulse sequence used. This was presumably because a faster spinning frequency was required to reduce the N–H dipolar interactions. In all cases, characteristic asymmetric doublets were observed for the ^1H – ^{14}N bonds, with the exception of the N-2 and N-3 nuclei in the imidazole ring of L-histidine hydrochloride monohydrate. Those two bonds exhibited broad asymmetric peaks, possibly being the result of strong hydrogen bonding.

The asymmetric peaks in the CRAMPS MAS spectra of amino acids were simulated by Naito et al.²³ using the computer programs based on the theoretical treatments

Figure 5 Lineshape of the CP MAS spectrum of a proton bonded to the peptide nitrogen nucleus in *N*-acetyl glycine. (a) Experimental spectrum obtained by using CRAMPS with the MREV-8 pulse sequence. (b) Computer-simulated spectrum obtained using a quadrupolar asymmetry parameter $\eta = 0.32$ and $e^2Qq_{zz}/h = -3.21$ MHz. (Reproduced by permission of the American Chemical Society from Naito et al.²³)

described earlier.^{14,16} In addition, it was necessary to multiply the quadrupole and Zeeman terms in the Hamiltonian by the scaling factors $S_m S_r$. The term S_m is the scaling factor for the multiple pulse scheme used, and $S_r = \frac{1}{2}(3 \cos^2 \theta - 1)$ is the scaling factor caused by a group rotation where θ is the angle between the rotation axis and the N–H direction. The lineshapes were simulated successfully. That of the peptide proton was well simulated (see Figure 5) using the ^{14}N coupling constant of -3.2 MHz and $\eta = 0.31$, the parameters having been determined in a single crystal ^{14}N NMR study on *N*-acetylvaline though the sign of the quadrupole coupling constant had been established previously from a comparison of the experimental and computer-simulated peptide carbon nuclei.¹⁶ In addition, it was necessary to interchange the assigned axes of the electric field gradient tensor so that the x axis was parallel to the N–H bond direction. The spectral peaks for the proton bonded to the imidazole nitrogen N nuclei were simulated using the ^{14}N coupling constants earlier determined from ^{14}N NMR single crystal studies. The simulated spectra showed that broad lines were to be expected and that a clear asymmetric doublet was not to be anticipated in this case. It was also to be expected that the proton bonded to the N-2 nucleus should have a broader lineshape than that for the N-3 nucleus. These predicted lineshapes were in good agreement with those observed experimentally.

The interesting ^{14}N -containing spin-pairs $^{14}\text{N} \equiv ^{15}\text{N}^+$ – and $^{15}\text{N} \equiv ^{14}\text{N}^+$ –yield unusual lineshapes.²⁴ It should also be mentioned that the ^{13}C MAS lineshapes of the parent compounds 5-methyl-2-[α - ^{15}N]diazobenzenesulfonic acid and its isotopomer with [β - ^{15}N] exhibit characteristic novel lineshapes. It was, however, possible to obtain approximate lineshape simulations for the ^{13}C – ^{14}N residual dipolar couplings even though the resulting ragged appearances of the simulations were clearly caused by the use of insufficient increments of the orientations of the angles β^Q and γ^Q in the calculations. Convolution of the two simulated spectra yielded a lineshape which was a good reproduction of the spectrum resulting from convoluting the observed ^{13}C MAS spectra of the two isotopomers. An apparent triplet lineshape was observed for the carbon nucleus bonded to the α - and β - ^{14}N nuclei of the diazo group, which arises from two different residual ^{13}C – ^{14}N dipolar couplings acting on the same carbon nucleus. It proved possible to simulate that feature.

Mention should be made of related studies of the lineshapes found for off-magic angle, or variable-angle, ^{13}C NMR spectra of compounds which exhibit ^{13}C – ^{14}N dipolar–quadrupolar interaction effects.²⁵ Though to some extent peripheral to the main thrust of this article, the phenomena described in those studies are of considerable interest.

1 INTRODUCTION

As explained in detail in *Magic Angle Spinning Carbon-13 Lineshapes: Effect of Nitrogen-14*, magic angle spinning does not always eliminate from spin- $\frac{1}{2}$ spectra the influence of dipolar coupling to quadrupolar nuclei. In particular, when quadrupolar energies are not negligible compared with Zeeman energies, spin- $\frac{1}{2}$ spectra may show splittings and/or lineshapes which arise from residual dipolar coupling to quadrupolar nuclei. This phenomenon was first discovered and thoroughly investigated for the (^{13}C , ^{14}N) nuclear pair, but it soon became apparent that the effect was more widespread, indeed ubiquitous. The present article will discuss a wide range of examples and will place particular emphasis on the perturbation approach, which is adequate to explain many cases. The discussion will be limited to the centers of gravity of what are, strictly speaking, powder bandshapes. The reader is referred to *Magic Angle Spinning Carbon-13 Lineshapes: Effect of Nitrogen-14* for details of more exact theory, for questions of powder bandshapes, and for all examples involving ^{14}N . The whole subject has received attention in a review article¹ which summarizes the theoretical approaches and also lists cases for many different nuclear spin pairs.

2 THEORETICAL BACKGROUND

Consider a pair of nuclei I and S , where the former has the spin quantum number $\frac{1}{2}$ and the latter is quadrupolar. For simplicity in this discussion, it will be assumed that the electric field gradient at S is axially symmetric, but the reader must be careful not to infer that the results below apply to the general case of $\mu \neq 0$. The phenomenon mentioned above can be traced to the influence of terms in the quadrupolar Hamiltonian involving nuclear spin operators other than $\hat{S}_z$. When Zeeman terms dominate, the energy levels of quadrupolar nuclei are properly characterised by the spin component quantum number m_S , associated with $\hat{S}_z$. Since the relevant Hamiltonian terms

have angular dependences $\frac{1}{2}(3 \cos^2 \theta_Q - 1)$, where θ_Q is the angle between the major principal axis of the quadrupolar tensor and the applied magnetic field ($\mathbf{B}_0$), their effects are averaged to zero by magic angle spinning at a fast enough rate. Moreover, in such circumstances, the only terms in the dipolar Hamiltonian connecting the quadrupolar nucleus with the spin- $\frac{1}{2}$ nucleus which are secular involve similar angular dependence $\frac{1}{2}(3 \cos^2 \theta_D - 1)$ where θ_D is the angle between $\mathbf{B}_0$ and the internuclear distance between the spin $\frac{1}{2}$ and the quadrupolar nuclei. Thus, magic angle spinning at a sufficiently high rate is enough to eliminate these dipolar interactions. Therefore, resonance frequencies in spin- $\frac{1}{2}$ MAS spectra are unaffected by dipolar interactions to quadrupolar nuclei in such circumstances. Similar considerations apply to anisotropy and asymmetry in the indirect ('scalar') coupling between a spin- $\frac{1}{2}$ nucleus and a quadrupolar nucleus: MAS suffices to remove the influence of such coupling components on the frequencies in the spin- $\frac{1}{2}$ spectrum, though the isotropic part of the coupling is retained.

However, when quadrupolar and Zeeman terms in the Hamiltonian become comparable, the situation is drastically changed. The detailed theoretical treatment using the full Hamiltonian is discussed in *Magic Angle Spinning Carbon-13 Lineshapes: Effect of Nitrogen-14*. Here, the perturbation treatment, which is frequently applicable, will be presented. The use of perturbation theory was pioneered by Olivieri and co-workers² for the (^{13}C , ^{14}N) case (though it was implicit in earlier treatments), and rapidly extended³ to situations involving higher-spin quadrupolar nuclei.

The spin- $\frac{3}{2}$ case is chosen here for illustration purposes. Consider the so-called 'alphabet expansion' of the dipolar and axially-symmetric quadrupolar interactions (Table 1). In the high-field approximation the Zeeman levels may be designated as $|m_S\rangle$, where $m_S = \frac{3}{2}, \frac{1}{2}, -\frac{1}{2}$ or $-\frac{3}{2}$. Under the influence of terms C , D , E , and F of the 'quadrupolar alphabet', these wavefunctions are mixed to become

$$|(-\frac{3}{2})'\rangle = |-\frac{3}{2}\rangle + a_1^* |-\frac{1}{2}\rangle - a_2^* |\frac{1}{2}\rangle \quad (1a)$$

$$|(-\frac{1}{2})'\rangle = -a_1 |-\frac{3}{2}\rangle + |-\frac{1}{2}\rangle + a_3^* |\frac{1}{2}\rangle - a_2^* |\frac{3}{2}\rangle \quad (1b)$$

$$|(\frac{1}{2})'\rangle = a_2 |-\frac{3}{2}\rangle - a_3 |-\frac{1}{2}\rangle + |\frac{1}{2}\rangle - a_1^* |\frac{3}{2}\rangle \quad (1c)$$

$$|(\frac{3}{2})'\rangle = +a_2 |-\frac{1}{2}\rangle + a_1 |\frac{1}{2}\rangle + |\frac{3}{2}\rangle \quad (1d)$$

where, in the perturbation approach, $a_1 = \langle \frac{1}{2} | \hat{\mathcal{H}}_Q | \frac{3}{2} \rangle / \gamma_s \hbar B_0$, $a_2 = \langle -\frac{1}{2} | \hat{\mathcal{H}}_Q | -\frac{3}{2} \rangle / 2\gamma_s \hbar B_0$ and $a_3 = \langle -\frac{1}{2} | \hat{\mathcal{H}}_Q | \frac{1}{2} \rangle / \gamma_s \hbar B_0$, etc.

The alphabet terms C and D are relevant for a_1 and a_3 whereas terms E and F are effective for a_2 . However, it can be shown that $a_3 = 0$ and that a_2 cannot affect the I spectrum. Now, because of the mixed nature of the Zeeman levels, terms C and D of the (I , S) 'dipolar alphabet' become secular, the additional energy contributions being

$$\begin{aligned} \langle (-\frac{3}{2})' m_I | \hat{\mathcal{H}}_D | (-\frac{3}{2})' m_I \rangle &= \langle (\frac{3}{2})' m_I | \hat{\mathcal{H}}_D | (\frac{3}{2})' m_I \rangle \\ &\quad - a_1 D m_I \end{aligned} \quad (2a)$$

$$\begin{aligned} \langle (-\frac{1}{2})' m_I | \hat{\mathcal{H}}_D | (-\frac{1}{2})' m_I \rangle &= \langle (\frac{1}{2})' m_I | \hat{\mathcal{H}}_D | (\frac{1}{2})' m_I \rangle \\ &\quad + a_1 D m_I \end{aligned} \quad (2b)$$

Table 1 The NMR Internal Hamiltonian: The Alphabet Expansion

Term	Geometric factor ^c	Spin factors ^c		
		Dipolar	Quadrupolar ^b	Connectivity
A	$1 - 3 \cos^2 \theta$	$\hat{I}_x \hat{S}_z$	$(\hat{I}_z)^2$	Secular
B	$-\frac{1}{4}(1 - 3 \cos^2 \theta)$	$\hat{I}_+ \hat{S}_- + \hat{I}_- \hat{S}_+$	$\hat{I}_+ \hat{I}_- + \hat{I}_- \hat{I}_+$	Flip-flop ^a
C	$-\frac{3}{2} \sin \theta \cos \theta \exp(-i\phi)$	$\hat{I}_x \hat{S}_+ + \hat{I}_+ \hat{S}_z$	$\hat{I}_z \hat{I}_+ + \hat{I}_+ \hat{I}_z$	Single quantum
D	$-\frac{3}{2} \sin \theta \cos \theta \exp(i\phi)$	$\hat{I}_x \hat{S}_- + \hat{I}_- \hat{S}_z$	$\hat{I}_z \hat{I}_- + \hat{I}_- \hat{I}_z$	
E	$-\frac{3}{4} \sin^2 \theta \exp(-2i\phi)$	$\hat{I}_+ \hat{S}_+$	$(\hat{I}_+)^2$	Double quantum
F	$-\frac{3}{4} \sin^2 \theta \exp(2i\phi)$	$\hat{I}_- \hat{S}_-$	$(\hat{I}_-)^2$	

^aSecular for the quadrupolar and homonuclear dipolar interactions, but nonsecular for heteronuclear dipolar interactions.

^bFor the axially symmetric case ($\eta = 0$).

^cThere are also constant numerical factors ($\hbar D$ for the dipolar case and $\hbar \chi / 2S(2S - 1)$ for the quadrupolar case).

where D is the dipolar coupling constant, $\gamma_I \gamma_S (\mu_0 / 4\pi) (\hbar / 2\pi) r_{IS}^{-3}$ (to be distinguished from the alphabet term D !). Therefore the energy levels are modified as shown in Figure 1, and the outer lines of the I multiplet will be shifted in one direction, while the inner lines will shift to the same extent but in the opposite direction. Of course the terms in the Hamiltonian also involve geometric factors which depend on the Euler angles connecting the dipolar and quadrupolar tensors with the magnetic field $\mathbf{B}_0$. Since these are *not* of the form $(3 \cos^2 \theta - 1)$, they are not eliminated by MAS although they are reduced. Thus each of the multiplet components in the I spectrum will be powder patterns under MAS. However, the structure of these powder patterns is not usually observed, and consequently the useful information normally comes from consideration of the centers of gravity of the bands. Of course the indirect coupling tensor $\mathbf{J}$ has some common features with $\mathbf{D}$, and therefore it will in principle also need to be considered.

Full evaluation for the general case results¹ in the following perturbation expression for the shift induced in the center of gravity of the spin- $\frac{1}{2}$ transition frequency associated with quadrupolar basis state m_S

$${}^2\Delta v(m_S) = \frac{3\chi}{20\nu_S} \left[\frac{S(S+1) - 3m_S^2}{S(2S-1)} \right] \times \left[Df(\alpha^D, \beta^D, \eta) - \frac{\Delta J}{3} f(\alpha^J, \beta^J, \eta) \right] \quad (3)$$

where $f(\alpha, \beta, \eta) = 3 \cos^2 \beta - 1 + \eta \sin^2 \beta \cos 2\alpha$, α and β are the relevant Euler angles (see Harris and Olivieri¹), η is the asymmetry in the electric field gradient, χ is the quadrupole coupling constant, ν_S is the Larmor frequency of the quadrupolar nucleus and ΔJ is the anisotropy in $\mathbf{J}$. The above equation assumes that $\mathbf{J}$ is an axially symmetric tensor. Simplifications result if there are further assumptions. In particular, if $\mathbf{J}$ and $\mathbf{D}$ are co-axial, and if η is ignored, the complete equation for the spin- $\frac{1}{2}$ transition frequency is

$$\nu(m_S) = \nu_I - m_S J_{\text{iso}} + \frac{3D'\chi}{20\nu_S} \left[\frac{S(S+1) - 3m_S^2}{S(2S-1)} \right] \quad (4)$$

where ν_I is the Larmor frequency of the spin- $\frac{1}{2}$ nucleus, J_{iso} is the isotropic part of $\mathbf{J}$, and D' is an effective dipolar coupling constant, incorporating the anisotropy in $\mathbf{J}$

$$D' = D - \frac{\Delta J}{3} \quad (5)$$

The second-order shift itself, $\nu(m_S) - \nu_I + m_S J_{\text{iso}}$, depends only on the square of m_S , and for $m_S = \pm S$ it is independent of S . It is therefore convenient to normalize effects to the shift of the 'outermost' lines, defined as

$$\Delta = -\frac{3}{10} \frac{\chi D'}{\nu_S} \quad (6)$$

This enables the second-order shifts of all lines to be written as

$${}^2\Delta v(m_S) = -\left[\frac{S(S+1) - 3m_S^2}{S(2S-1)} \right] \Delta \quad (7)$$

Table 2 lists the shifts of all lines, for various half-integral values of S , in terms of Δ .

Figure 1 Energy-level diagram for an IS nuclear spin pair with $I = \frac{1}{2}$, $S = \frac{3}{2}$ to show the perturbations induced by quadrupolar and dipolar interactions. The extent of the perturbations is greatly exaggerated. It is assumed that γ_I , γ_S , and J_{iso} are all positive

Table 2 Second-Order Shifts in the Spectra of Spin- $\frac{1}{2}$ Nuclei Arising from Coupling to a Half-Integral Quadrupolar Nucleus S^a

S	m_S				
	$\pm\frac{1}{2}$	$\pm\frac{3}{2}$	$\pm\frac{5}{2}$	$\pm\frac{7}{2}$	$\pm\frac{9}{2}$
$\frac{3}{2}$	-1	1			
$\frac{5}{2}$	$-\frac{4}{3}$	$-\frac{1}{3}$			
$\frac{7}{2}$	$-\frac{5}{2}$	$-\frac{1}{2}$	1		
$\frac{9}{2}$	$-\frac{7}{3}$	$-\frac{1}{3}$	$\frac{1}{3}$	1	
$\frac{11}{2}$	$-\frac{8}{3}$	$-\frac{1}{3}$	$-\frac{1}{6}$	$\frac{1}{3}$	1

^aNote: The values are normalized to the shift of the outermost lines as expressed in equation (6).

3 CONSEQUENCES OF PERTURBATION THEORY

A number of significant features can be understood from equations (3)–(7).

1. While perturbation theory holds, second-order shifts are inversely proportional to B_0 , so that no new information is obtained by using several spectrometers. However, such experiments can be used to check that the origin of splittings in the spectra does indeed involve second-order effects, since the behavior with B_0 differs from that of splittings caused by either J_{iso} or differences in chemical shifts.
2. Since second-order shifts depend on m_S^2 , their values occur in pairs, with the outermost multiplet lines moving most. Figure 2 illustrates the situation as a function of $\chi D/\nu_S$ when $\Delta J = 0$.
3. The average second-order shift is zero, so the isotropic chemical shift is simply obtained by averaging the frequencies of all the lines.
4. The isotropic coupling constant, $|J_{\text{iso}}|$, is also readily obtained as the average spacing between lines, though care must be taken if there is any crossover of frequencies. The value of $|J_{\text{iso}}|$ is also available from the central spacing $|\nu(m_S = \frac{1}{2}) - \nu(m_S = -\frac{1}{2})|$.
5. Since the innermost lines shift in the opposite direction to the effect on the outermost lines, there is a 'bunching' of lines at one end of the spectrum. The extent of coalescence is more apparent for lower values of S for a given $\chi D/\nu_S$. The sense depends on the sign of Δ , and in favorable cases it gives important information on relative signs.
6. In particular, if $\mathbf{J}$ and $\mathbf{D}$ are co-axial the following general rule results: 'bunching' occurs to low frequency (i.e. Δ is positive) if *either* χ is negative (with D and D' of the same sign) *or* χ is positive (with D and D' of opposite signs). An analogous statement can be made if Δ is negative. This rule takes into account the effects of signs of magnetogyric ratios. Thus, if the magnitude and sign of χ is known, together with r_{IS} , and if η is ignored, then ΔJ can be derived unambiguously. However, if only r_{IS} and $|\chi|$ are available, two possible values of ΔJ can be calculated but they cannot be distinguished.
7. When perturbation theory holds, neither the magnitude nor the sign of J_{iso} influences Δ .
8. If the value of $|J_{\text{iso}}|$ is negligible compared to linewidths, then there will be $S + \frac{1}{2}$ lines. The relative frequencies at which 'bunching' takes place will give the sign of χ . The magnitude of Δ will enable r_{IS} to be determined if $|\chi|$ is known, and vice versa. However, $S = \frac{3}{2}$ is a special

Figure 2 Second-order shifts in spin- $\frac{1}{2}$ MAS spectra arising from coupling to a quadrupolar nucleus S , as a function of the parameter $\chi D'/\nu_S$ under a perturbation approach according to equation (7): (a) $S = \frac{3}{2}$; (b) $S = \frac{5}{2}$. A positive value of Δ is assumed

Figure 3 Second-order shifts in spin- $\frac{1}{2}$ MAS spectra arising from coupling to a quadrupolar nucleus $S = \frac{3}{2}$ as a function of the parameter $\chi D'/\nu_S$ under a perturbation approach according to equation (7): (a) $J_{\text{iso}} = 0$; (b) $-J_{\text{iso}} > 0$. A positive value of Δ is assumed

case, since a 1:1 doublet will be seen [Figure 3(a)], of spacing $\frac{3}{10}(\chi D/\nu_S)(3 \cos^2 \beta^D - 1 + \eta \sin^2 \beta^D \cos 2\alpha^D)$ in the general case, and information on the sign of χ is lost.

9. The same denominator in equation (7) reflects the fact that the validity of the perturbation approach depends on $\chi/2S(2S - 1)\nu_S$, higher spins are more accurately treated than lower spins for equivalent values of χ .

4 RESULTS AND DISCUSSION

Many examples are now known where perturbation theory is reasonably applicable. In particular, the (^{119}Sn , $^{35/37}\text{Cl}$) situation is appropriate^{3,4} since in such cases $|\chi|$ is generally modest (~ 35 MHz). Thus even for a 4.7 T spectrometer, the perturbation parameter $\chi/2S(2S - 1)\nu_S$ is only in the region of 0.30. The splitting arising from $|J_{\text{iso}}|$ cannot be ignored. However, since chlorine is monovalent, coaxiality of $\mathbf{J}$ and $\mathbf{D}$ is a reasonable approximation for directly-bonded Sn–Cl groups except when chlorine is in a bridging situation. In fact,

Figure 4 Tin-119 CP MAS NMR spectra at 74.63 MHz for (a) $(\text{PhCH}_2)_3\text{SnCl}$ and (b) Et_2SnCl_2 , showing the second-order effects of coupling to the chlorine nuclei.⁴ The markers are at 1 kHz and 0.5 kHz intervals for (a) and (b), respectively

a typical spectral pattern is a 1:1:2 triplet with relative spacings 2:1 [Figure 4(a)], which is strictly the case only when $|J_{\text{iso}}| = 2\Delta$. Values of $|J(\text{Sn}, \text{Cl})|$ have therefore been derived, as have approximate data for ΔJ . When more than one chlorine is coupled to the same Sn, simple convolution suffices to predict the spectral appearance. If the chlorines are equivalent, then $|J_{\text{iso}}| = 2\Delta$ leads to a 1:2:4:1:4:4 multiplet (with the first spacing twice the others), such as has been observed [Figure 4(b)] for Et_2SnCl_2 .⁴

Cases involving ^{31}P coupled to metal nuclei are also common, and have been shown^{5,6} to occur for a range of S -spin metals, e.g. $^{63/65}\text{Cu}$ ($S = \frac{3}{2}$), ^{55}Mn ($S = \frac{5}{2}$), ^{59}Co ($S = \frac{7}{2}$), and ^{93}Nb ($S = \frac{9}{2}$). Figure 5 shows an example where the second-order effects are relatively small. In a number of such cases perturbation theory is not appropriate, and in others questions of nonaxiality reduce the usefulness of the observed second-order effects. However, the case of $\text{Mn}_2(\text{CO})_9\text{PPh}_3$ proved⁶ to be appropriate, since the molecular symmetry has axiality and spinning sideband analysis indicates that this is retained in the solid state. Such an analysis also gives a value for $|D'|$, so that $|\chi|$ can be derived (42 MHz). The value of $\chi/2S(2S - 1)\nu_S$ for a spectrometer operating at 7.1 T is thus 0.028, which confirms that perturbation theory is applicable. Several (^{31}P , $^{63/65}\text{Cu}$) examples have been analyzed⁷ using perturbation theory to yield data for $\Delta J \sim 0.6$ kHz.

Numerous other examples of residual dipolar coupling have been reported, some of which come into the category of a perturbation treatment. In particular, examples of (^{13}C , ^2H) have been given.^{1,8,9} Although ^2H has a low value of χ , the residual effects of dipolar coupling are appreciable because r_{CH} is small and hence D is relatively large. With rigid molecules,^{1,8} there is a nice contrast to the (^{13}C , ^{14}N) case since, although 2:1 doublets are observed in both instances, the origins differ. For the (^{13}C , ^{14}N) pair J_{iso} can usually be ignored, so there is overlap for the lines connected to states $|+1\rangle$ and $| -1\rangle$ for ^{14}N , whereas for (^{13}C , ^2H), the overlap is of transitions involving $|0\rangle$ and $| -1\rangle$ for ^2H . The latter situation arises coincidentally because $|J_{\text{iso}}(^{13}\text{C}, ^2\text{H})|$ is approximately equal to $\frac{9}{10} D\chi/\nu_S$. The spectra have a different appearance⁹ for inclusion compounds of urea and thiourea with deuterated guest molecules, such as straight-chain alkanes and corresponding carboxylic acids. The guest molecules are relatively mobile, so that values of $\chi(^2\text{H})$ are substantially reduced (to ca. 50–70 kHz for CD_2 groups) by averaging. Second-order effects on the ^{13}C spectra are therefore relatively modest, simply resulting in a small asymmetry in the splittings

Figure 5 Phosphorus-31 CP MAS NMR spectra at 81.0 MHz for $(\text{C}_5\text{H}_5)(\text{Me}_3\text{P})\text{Cl}_2\text{Nb}=\text{N}(o\text{-tBuC}_6\text{H}_4)$, showing the second-order effects of coupling to the niobium nucleus: the multiplet spacing decreases slightly from high to low frequency. The lines outside the main decet are spinning sidebands. The markers are at 1 kHz intervals

of the 1:2:3:2:1 quintet patterns. The spectra can be used to determine, at least qualitatively, the relative values of χ at different positions in a chain, which in turn depend on variations in local molecular mobility.

Of course, the appearance of splittings arising from either dipolar coupling, whether residual or full, or indirect coupling is contingent upon the lifetimes of the quadrupolar spin states being long compared with the frequency separations in the spin- $\frac{1}{2}$ spectra. If spin–lattice relaxation times of the quadrupolar nuclei become sufficiently short, the result is ‘self-decoupling’ (such as is frequently observed in solution state situations). In such cases a single line will be seen in the spin- $\frac{1}{2}$ spectrum. This is the situation¹⁰ for the ^{31}P spectrum of PCl_5 where sharp singlets are observed for the PCl_4^+ and PCl_6^- ions at room temperature but multiplets at low temperature. Of course, molecular motion (e.g. rotation of ions, as for PCl_5) may affect residual dipolar splittings both directly (by averaging D) and indirectly (by relaxing the S nucleus). ‘Self-decoupling’ can in principle also occur because of chemical exchange involving I – S bond breaking.

5 DEPARTURE FROM PERTURBATION THEORY

The first clear case of effects of dipolar coupling residual which did not involve the (^{13}C , ^{14}N) nuclear pair concerned the (^{31}P , ^{63}Cu) nuclei in bis(triphenylphosphine)copper(I) and related complexes, presented by Menger and Veeman.⁵ These authors published detailed theory, but the situation was beyond the validity of perturbation theory. Many examples involving the (^{31}P , ^{63}Cu) pair have since come to light, though some are susceptible to the perturbation approach.

The (^{13}C , $^{35/37}\text{Cl}$) case is interesting.^{11,12} Although there are simplifying features, since chlorine is univalent (and hence coaxiality of $\mathbf{J}$ and $\mathbf{D}$ can be assumed) and $J(\text{C}, \text{Cl})$ is negligibly small, the value of $|\chi|$ is sufficiently large (ca.

Figure 6 Carbon-13 CP MAS NMR spectra of sodium monochloroacetate: (a) 75.4 MHz; (b) 50.3 MHz, showing the second-order effects of coupling to chlorine.¹² The insets show expansions of the carboxyl region. The asterisks denote spinning sidebands

–70 MHz) that departures from perturbation theory can be observed. At modest magnetic fields (7.1 T and above), the 1:1 doublet predicted by perturbation theory is indeed observed [Figure 6(a)], but the splitting is smaller than predicted and is not inversely proportional to B_0 . However, it has been shown¹³ by simulation using exact theory that for the case $S = \frac{3}{2}$ the doublet splitting, s , can be adequately represented in the range $0.8 < R = |\chi/\nu_S| < 3.0$ by the cubic polynomial

$$s = D(0.581R + 0.033R^2 - 0.021R^3) \quad (8)$$

A cubic equation for s has also been derived for the $S = \frac{3}{2}$ case in which J_{iso} cannot be ignored.

For the (^{13}C , $^{35/37}\text{Cl}$) case, even equation (8) is inadequate at 4.7 T, since a broad 2:1:1 triplet is both predicted and observed^{11,12} [Figure 6(b)]. Figure 7 shows the theoretical line positions (centers of gravity) as a function of R for the case $I = \frac{1}{2}$, $S = \frac{3}{2}$ for positive χ and in the absence of $\mathbf{J}$. At high values of R , four lines are expected, and this links up with the expectation from inverse perturbation theory discussed below.

Molecular-level motion has a drastic effect on the ^{13}C spectra of sodium chloroacetates.¹² For the monochloro compound a clear doublet is seen for both the CH_2Cl and carbonyl carbons at 7.1 T and above, with the expected 2:1:1 triplet at 4.7 T. However sodium trichloroacetate shows a sharp line for each carbon at 7.1 T, not only at room temperature but also down to 163 K. The reason for this behavior undoubtedly lies in the facile internal rotation of the $\text{C}-\text{CCl}_3$ group.

Figure 7 Line positions (centers of gravity, units of D) for a spin-1/2 nucleus coupled to a spin-3/2 nucleus as a function of $R = \chi/\nu_S$ as obtained¹³ by the full theory for positive χ and assuming $J_{\text{iso}} = \Delta J = \eta = \beta^D = 0$

When J_{iso} needs to be taken into consideration and perturbation theory is inadequate, it has been shown¹³ that the sign of J_{iso} can be obtained from the spectrum (if the sign of χ is known). Thence $J(^{63}\text{Cu}, ^{31}\text{P})$ has been found¹³ to be negative.

6 QUADRUPOLEAR COUPLING DOMINANT

Olivieri has considered^{14,15} the case where the quadrupole coupling constant is very large. The dipolar and indirect couplings will still transfer the quadrupole information to the spin- $\frac{1}{2}$ nucleus under MAS conditions, giving rise to splittings in the spectra. For the case where $\mathbf{J}$ is axially symmetric and the three tensors $\mathbf{D}$, $\mathbf{q}$, and $\mathbf{J}$ are all co-axial, Olivieri showed¹⁴ that a quartet results when $S = \frac{3}{2}$. Each component is a powder pattern, with the centers of gravity forming two doublets with splittings, independent of the applied magnetic field, given by

$$s(\pm\frac{1}{2}) = |1.709J_{\text{iso}} + D'| \quad (9a)$$

$$s(\pm\frac{3}{2}) = \frac{3}{2}|2D' - J_{\text{iso}}| \quad (9b)$$

When the Zeeman S term begins to be significant with respect to the quadrupolar interaction, an inverse perturbation approach ('inverse' when compared to the considerations of Section 2 above) may be used.¹⁴ In this case equations (9a) and (9b) need to be modified, and the four centers of gravity are

$$\langle \Delta\nu(\pm\frac{1}{2}) \rangle = \mp(0.8546J_{\text{iso}} + 0.5D')$$

$$-2(J_{\text{iso}} + D')\frac{\nu_S}{\chi} \quad (10a)$$

$$\langle \Delta\nu(\pm\frac{3}{2}) \rangle = \pm\frac{3}{4}(2D' - J_{\text{iso}}) + 2(J_{\text{iso}} + D')\frac{\nu_S}{\chi} \quad (10b)$$

The spectrum is no longer symmetric, and the sense of the asymmetry depends on the relative signs of $J_{\text{iso}} + D'$, ν_S , and χ . Olivieri has also extended calculations¹⁵ of this type to

situations where $\mathbf{q}$ is not axially symmetric and for arbitrary relative orientations of $\mathbf{q}$ and $\mathbf{D}$.

Frequently, large χ implies the likelihood of rapid spin–lattice relaxation and therefore self-decoupling of S from the spin- $\frac{1}{2}$ nucleus in question. However, (^{13}C , $^{79/81}\text{Br}$) systems have been shown¹⁶ to approach the inverse perturbation case, and an example of a (^{31}P , ^{201}Hg) spin pair (with $D \ll J_{\text{iso}}$ in magnitude) even nearer the low-field limit has been reported.^{15,17}

1 INTRODUCTION

Magnetic equivalence arises from symmetry. It is convenient to divide symmetry into two parts. The first is the point group symmetry of the molecule (or ion). The second is the symmetry that involves rapid intramolecular motions such as internal rotation of parts of the molecule against other parts, molecular inversion, or shifting of bonds between atoms in the molecule. As the temperature is lowered, these motions or rearrangements may slow down so much that nuclei (or sets of nuclei) that were equivalent at higher temperature become magnetically nonequivalent. (Magnetic equivalence that is achieved by interaction between molecules and/or intermolecular events is excluded from discussion in this article.)

Rapid processes are those by definition that occur with a frequency greater than the chemical shift difference between the NMR signals from the nuclei if they were nonequivalent. The spectrum that occurs at higher temperature when processes are rapid and the nuclei are equivalent is known as the *fast exchange spectrum*. The spectrum at lower temperature and when processes are slow is known as the *slow exchange spectrum*. The spectra at intermediate temperatures are said to be *intermediate exchange spectra*. Typically signals are broadened to become perhaps almost featureless humps for nuclei in the temperature region of intermediate exchange. Signal shape analysis of broadened signals can yield rate

data and kinetic parameters. The kinetic window for signal shape analysis can vary substantially for different situations. However, typically rates of $10\text{--}1000\text{ s}^{-1}$ can be determined by signal shape analysis. (The free energy of activation, $\Delta G^\ddagger$, as reported in the literature for various processes is quoted in this article. The temperature is always 298 K, unless otherwise noted.)

For convenience in discussion, point group symmetry will be referred to as *static symmetry*. The effect of internal motions will be referred to as *dynamic symmetry*. In fact, manifestation of dynamic symmetry is commonly called DNMR (dynamic NMR).

The operations of static symmetry and dynamic symmetry can be brought together to form a *permutation group* for the nuclei or groups of nuclei under discussion. This may seem strange since static symmetry depends only on geometry and does not actually move nuclei, while dynamic symmetry depends on actually moving nuclei. However, mathematically there is no qualitative distinction between the outcome of the two kinds of symmetry. In any event the nuclei are permuted (or in more common language they are exchanged). Permutation group theory is not discussed as such in this article, but it will be useful to use some of the ideas of permutation groups.

It is important to note that NMR of itself does not necessarily specify uniquely the dynamic physical process that permutes nuclei in any given case. It may, however, reveal which nuclei are exchanging with which nuclei. The detection of mutual exchange will be discussed in the main body of this article. But any analysis as to detailed mechanism requires additional information or theory outside the NMR experiment. However, a knowledge of mutual exchange may rule out certain mechanisms from a list of otherwise plausible mechanisms.

In spite of this caveat as to the limits of mechanistic information from NMR alone, the main article is organized to some extent around demonstrations of rotation around bonds, molecular inversion, and other specific internal motions, shifting of bonds, or combinations of such as these. The choice of interpretation of the nuclear exchange has always been assisted by outside considerations, even though these considerations may not be explicitly stated in the discussion that follows.

Individual studies have been selected for discussion in this article to represent principles. There is no attempt to give a review-like coverage of the very large literature that is continuing to emerge on the subject. Selection has not been made on the basis of clear superiority of one report over similar reports. The literature is too large and choice too subjective to guarantee that the selection has been made entirely on the basis of merit or of scientific importance.

Finally, a large share of the literature covered in this article was published in the approximate period from 1960 to 1975. The principles that were established in that period are now almost a matter of routine, but of course with newly interesting manifestations. Section 16, General References, refers to a variety of reviews and literature collections and should be consulted for a much wider coverage of magnetic equivalence and dynamic NMR than was possible to give in composing the present article. Also the bulk of the NMR studies have been undertaken by proton NMR methods. Unless otherwise specified or obvious, NMR stands for proton NMR in this article.

2 A HYPOTHETICAL MOLECULE

Some of the discussion in the Introduction can be illustrated with simple examples. The first example deals with a hypothetical molecule (1). So long as the R^1 , R^2 , and R^3 groups are all different, the carbon atom, C^* , is asymmetric and the molecule has no symmetry plane. As a consequence, the hydrogen atoms, H_A and H_B , are nonequivalent since there is no static symmetry between them. Inversion of the asymmetric carbon atom would be a dynamic symmetry operation, but inversion of such a carbon atom is much too slow by many orders of magnitude to be an effective dynamic symmetry operation.

It might be supposed that rotation around the bond between the carbon atoms could constitute a dynamic symmetry operation, but this is not correct. Rapid rotation around that bond might tend to average out the environments of the hydrogen atoms, but the averaging could never be complete. It is suggested here that this last point is best demonstrated by experimenting with molecular models. On the other hand, if any two of the R^1 , R^2 , or R^3 groups were the same, there could be a symmetry plane between the hydrogen atoms. This static symmetry element would make the hydrogen atoms magnetically equivalent.

The usual twisting and turnings, rotations and vibrations of the rest of the molecule would ordinarily be much too rapid on the NMR timescale to destroy this equivalence. Variable temperature NMR studies are at the heart of much of the discussion of magnetic equivalence or the lack of it. If an internal rearrangement is so rapid that it cannot be 'frozen out' at the lowest experimentally attainable temperature, then it is just part of the background. It does not stand out as a dynamic symmetry operation, the effect of which is amenable to study by variable temperature NMR.

Given the asymmetric carbon atom, the hydrogen atoms are *diastereotopic*. This term will be used frequently in later discussions. In principle any geminal species can be diastereotopic. Isopropyl radicals are often included in molecules chosen for study. The methyl groups within an isopropyl group can be diastereotopic. Molecular inversion is the only dynamic operation that can render the methyl groups equivalent. If the methyl groups remain nonequivalent, then rapid inversion is not occurring. Of course other geminal pairs can serve the same purpose but their utility is usually lessened by the complex spectra that can occur, while methyl nonequivalence can lead to signal patterns that are easy to analyze, often at a glance.

3 DIMETHYLFORMAMIDE: INTERNAL ROTATION

The observation by Phillips¹ of the effect of temperature on the proton magnetic resonance spectrum of *N,N*-dimethylformamide and its explanation as internal rotation is one of the earliest records of intramolecular exchange in NMR.

The core framework of amides is planar. There is partial double bond character in the carbonyl-to-nitrogen bond (the amide bond). Pauling² calculated the resonance energy to be 88 kJ mol⁻¹. For present purposes, resonance energy and the partial double bond character are manifest as the barrier to rotation around the amide bond.

Phillips observed that there is only one methyl signal at the fast exchange limit, but that this signal splits into two methyl signals at the slow exchange limit. He explained this behavior as being due to rapid rotation around the amide bond at higher temperature with the rotation slowing down as the slow exchange limit is reached at lower temperature.

Gutowsky and Holm³ utilized the techniques of Gutowsky's earlier signal shape studies to determine the rate of rotation in dimethylformamide. They obtained a $\Delta G^\ddagger$ value of 92 kJ mol⁻¹. Since this pioneering work, there has been and continues to be a veritable torrent of applications to a large variety of intermolecular as well as intramolecular rate problems.

The symmetry considerations that are involved are straightforward. In the planar ground state, both methyl groups lie in the amide plane. Since there is no static symmetry element between the methyl groups, they are nonequivalent in the ground state. One methyl group is *cis* to the carbonyl oxygen and the other is *trans*. Rapid rotation around the amide bond is the dynamic symmetry operation that makes the methyl groups equivalent.

This set of symmetry considerations applies for amides in general and even more generally to rotation around the bond between trigonally bonded atoms in a variety of molecules that have a planar ground state. On the other hand, biphenyls, as examples, have the rotating parts in an out-of-plane ground state, and the barrier to rotation is substantially steric rather than electronic as it is in rotation around the amide bond.

4 BIPHENYL-LIKE ROTATION IN CERTAIN ANILIDES

Dynamic NMR of anilides with unsymmetrical substitution in the benzene ring demonstrates how a missing static symmetry operation can be replaced by a dynamic symmetry operation and magnetic equivalence is then achieved.

In ground state anilides of the general type (2) the benzene ring is perpendicular to the amide plane. If the ring is symmetrically substituted, the perpendicular plane through the ring is a symmetry plane (a static symmetry element). If both *ortho* substituents are not the same, this symmetry plane is lost, a chiral center is established, and the molecule becomes chiral. This situation was first reported by Adams and his students⁴ well before the advent of NMR in chemistry.

Figure 1 Double proton signals at 40 °C of an anilide dissolved in $\text{CHCl}_2\text{CHCl}_2$. [Reprinted with permission from Siddall and Stewart, *J. Phys. Chem.*, **73**, 40. Copyright (1969) American Chemical Society]

Rotation around the benzene-to-nitrogen bond is generally slow on the NMR timescale at room temperature, but becomes rapid at elevated temperature. Rapid rotation then becomes a dynamic symmetry operation and substitutes for the lost symmetry plane. (Generally, the *cis/trans* isomerism due to slow rotation around the carbonyl-to-nitrogen bond is not observed in anilides of this type except in formanilides. Probably this is due to the predominance of one geometric isomer over the other to the point of excluding the lesser isomer from observation.)

This situation is demonstrated in a striking manner if a second chiral center is introduced into the anilide molecule.⁵ With two chiral centers the molecule exists as two diastereoisomers. In the slow exchange limit each of the two isomers exhibits its own set of NMR signals. This in effect doubles the signals in the NMR spectrum as can be seen in Figure 1.

However, raising the temperature increases the rate of rotation around the benzene-to-nitrogen bond and the doubled signal sets coalesce into a single set of signals. The single signal is the average over the rapid equilibrium between the two isomers. Rapid rotation has substituted for the lost symmetry plane and leads to magnetic equivalence.

5 ROTATION OF METHYL GROUPS AS A DYNAMIC SYMMETRY OPERATION

The barrier to rotation of methyl groups is typically quite small, 12–13 kJ mol^{-1} . As a consequence, rotation of the methyl group is very rapid on the NMR timescale and is usually not explicitly considered as a dynamic symmetry operation in evaluating symmetry for NMR purposes. However, extreme crowding in 1-*t*-butyl-5,6,7,8-tetrachloro-1,4-dihydronaphthalene 1,4-endoxide (**3**) slows methyl group rotation down sufficiently to be detectable.⁶

At room temperature, the *t*-butyl group gave a sharp singlet. At $-60\text{ }^{\circ}\text{C}$, the methyl groups within the *t*-butyl group are nonequivalent and the original singlet becomes three sharp singlets. Rotation around the bond to the *t*-butyl group evidently has slowed down. As the temperature was lowered still further to $-121\text{ }^{\circ}\text{C}$ and finally to $-133\text{ }^{\circ}\text{C}$, two of the three methyl signals broadened almost to the point of decoalescence, while the singlet from the third methyl group remained little changed. Apparently the temperature could not be lowered sufficiently to give the slow exchange spectrum. The authors examined possibilities other than slow methyl rotation as explanations for the broadening, but were able to dismiss these other possible explanations.

6 GEARED ISOPROPYL GROUPS

Rapid rotation of isopropyl groups is usually automatically taken for granted as part of a big background of rapid internal molecular motions that are not singled out as dynamic symmetry operations, since they are rapid on the NMR timescale at accessible temperatures. However, there is considerable evidence that isopropyl rotation can be slow, especially if isopropyl groups are in close enough proximity to each other to interact sterically. This steric interaction apparently can take the form of synchronous rotation. Such isopropyl rotations have been quite aptly labeled as geared rotation⁷ or cogwheeling. Furthermore, the rotation of other groups that are adjacent to the geared isopropyl groups can

be slowed because of steric interactions with the isopropyl groups.

In the molecule described below, benzyl group rotation is slowed because of interaction with the isopropyl groups. (The NMR studies were made both with proton NMR and with carbon-13 NMR. The two spectroscopies substantiated each other in detail. This being the case and in the interest of economy in discussion, only the proton behavior is described below.)

The room temperature spectrum⁷ of 1,3-dibenzyl-4,5-diisopropyl-2-thione (**4a**, **4b**) is just as would be expected. At highest frequency, the benzene ring protons give a multiplet; moving to low frequency, the methylene protons give a singlet, then there is the methine septet, and finally at lowest frequency there is the expected methyl doublet. The static symmetry is C_{2v} . The molecule lies in one plane. The plane perpendicular to the molecular plane makes the isopropyl groups equivalent as whole groups and also the benzyl groups equivalent as whole groups. The molecular symmetry plane makes the protons within a methylene group equivalent and the methyl groups within an isopropyl group equivalent.

The spectrum at -112°C is anything but routine. The C_{2v} symmetry is destroyed. There are no longer any symmetry planes nor a C_2 axis. Methylene protons give four separate AB patterns and are clearly diastereotopic. The methine signals have disappeared into baseline noise, but there are four methyl doublets. The increase to four AB patterns definitely shows that there are four different low temperature environments for the methylene groups and eight environments for the methylene protons.

The existence of only four methyl doublets from the isopropyl groups might be unexpected. If there are eight environments for the methylene protons, eight environments would be expected for the methyl groups. This could lead to eight doublets rather than just four. Precise signal overlap to give just four pairs of doublets could be an explanation, but does require an uncomfortable degree of coincidence. However, since no alternative explanation is readily forthcoming, the discussion will be continued, while ignoring this difficulty, which is what the authors of the paper did.

The spectra taken between -20°C and -90°C indicate that more than one rate process is taking place. The process that is observed below -20°C is assigned to the synchronous rotation of the isopropyl groups. At lower temperature, the process of rotation around the bond of one of the benzyl groups is being slowed down. At still lower temperature, the rotation of the other benzyl group is slowing. The $\Delta G^{\ddagger}$ value was calculated to be 48 kJ mol^{-1} at 223.6 K for the isopropyl process, and 45 and 36 kJ mol^{-1} for the two different benzyl rotations.

The process shown below is central to rationalizing the spectral observations. The isopropyl groups, acting as gears, tend to lock into one or the other of two positions. The

positions are mirror images of each other. The gears rotate rapidly on the NMR timescale at room temperature. The gears lock and unlock so quickly that the locked positions average out. At about -20°C the lock–unlock rotation slows down to the slow exchange limit as far as the isopropyl rotations are concerned. Meanwhile, the rotamer lifetime of the benzyl groups is still very short, still at rapid exchange. Many benzyl rotations occur during the lifetime of one lock of the isopropyl gears.

As the temperature is lowered still further, first one of the benzyl rotations slows to the slow exchange limit. Finally, at still lower temperature, the other benzyl rotation slows to the slow exchange limit. Once all three of these rotations have slowed enough, the slow exchange NMR spectrum obtains.

In ground states a benzyl rotamer can have two positions. In one position the benzene ring is above the molecular ring plane. In the other position the benzene ring is below that plane. This leads to *syn/anti* isomerism, both benzene rings on one side of the ring plane or one benzene ring on one side of the plane and the other on the other side of the plane. In each of the *syn/anti* isomers the benzyl groups are in different environments and within each methylene group the protons are in a different environment. Since $2 \times 2 \times 2 = 8$, there are eight proton environments and four AB quartets.

As the temperature is raised from the overall slow exchange limit, each of these dynamic symmetry operations are involved to give finally the fast exchange spectrum, to result in C_{2v} molecular static symmetry, and to give magnetic equivalences consistent with that symmetry.

7 AN AMINE/AMINE HYDROCHLORIDE EQUILIBRIUM WITH AMINE INVERSION

This example⁸ is interesting enough that it is included even though it may be a violation of the restriction to intramolecular events as stated in the Introduction. The discussion involves the static symmetry and also molecular inversion as a dynamic symmetry operation.

Nitrogen inversion in simple acyclic amines and with hydrocarbon substituents is usually too rapid to be observed directly by NMR. On the other hand, inversion of the hydrochloride of amines is very slow and magnetic equivalence is dictated by static symmetry alone. However, with an amine/amine hydrochloride equilibrium, nonequivalent protons in the hydrochloride can become equivalent in the amine. The amine in this example is dibenzylmethanamine.

The symmetry plane between the benzyl groups in the amine hydrochloride makes the benzyl radicals equivalent as entire radicals, but there is no static symmetry element that makes the protons of the methylene group magnetically equivalent within a benzyl radical. As a consequence the methylene protons with the methylene groups give an AB quartet. Inversion is much too slow within the hydrochloride to act as a dynamic symmetry operation.

On the other hand, inversion of the amine is rapid and acts as a dynamic symmetry operation to make the methylene protons equivalent. As the pH of the hydrochloride solution is raised, enough amine exists in the equilibrium mixture that the methylene AB quartet coalesces as the methylene protons become equivalent.

Since inversion occurs only during the amine lifetime, and the amine/amine salt equilibrium is fast, the exchange of methylene proton identities is given by $k(\text{exchange}) = k(\text{inversion}) \times (\text{amine})/[(\text{salt}) + (\text{amine})]$. With a pH of 2.5, using the $\text{p}K_{\text{a}}$ value of the amine as 7.5 and obtaining $k(\text{exchange})$ from signal shape analysis, the authors were able to calculate the inversion rate of the amine as $2 \times 10^5 \text{ s}^{-1}$. In effect the salt sequestered enough of the amine to make the inversion rate measurable.

8 EXCHANGE IN AN IRON HYDRIDE

Inorganic compounds can be a very rich source for all sorts of NMR studies. The examination of the temperature-dependent proton spectra and ^{31}P spectra of $\text{H}_2\text{Fe}[\text{P}(\text{OC}_2\text{H}_5)_3]_4$ illustrates this richness.⁹ (Of the proton spectra only the hydride part is relevant to the discussion. The spectra of ethyl protons are omitted.)

The compound exists as the *cis* isomer, (5), where the Ps represent ligand triethyl phosphite molecules and the Hs the ligand hydrogen atoms. The subscripted numbers will be used in the continued discussion. Because of space limitations, the discussion is drastically curtailed. Readers may wish to consult the original paper.

At 68°C , the spectrum of the hydride hydrogens is a binomial quintet which indicates that the protons are magnetically equivalent as are the phosphorus atoms. The proton-decoupled phosphorus spectrum is just one singlet which also indicates that the phosphorus atoms are equivalent. It must be that some exchange processes are rapid enough at this temperature to be dynamic symmetry operations that lead to the patterns of magnetic equivalence.

At -50°C , the magnetic equivalence of the phosphorus atoms has disappeared. The proton-decoupled phosphorus spectrum gives an A_2B_2 pattern which is just what would be expected from C_{2v} symmetry for the *cis* isomer.

The low temperature proton spectrum for the hydride hydrogens is a deceptively simple triplet of doublets which represents an $\text{AA}'\text{XX}'\text{Y}_2$ pattern (A for protons, X and Y for phosphorus). The authors found six different coupling constants which is consistent with such a pattern.

As the temperature is lowered from 68°C , the three central peaks of the proton quintet broaden, as would be expected if the relevant exchanges were occurring. However, the wing peaks of the quintet remain sharp and unaffected by exchange. This shows that two of the phosphorus atoms remain equivalent as the temperature is lowered. The axial phosphorus atoms are magnetically equivalent and are the Y_2 part of the $\text{AA}'\text{XX}'\text{Y}_2$ spectrum. On the other hand, the equatorial phosphorus atoms are the XX' part of the spectrum and are not magnetically equivalent.

The phosphorus spectra at intermediate temperatures were compared with calculated spectra assuming various phosphorus atom exchange schemes. The only exchange scheme that

fits the experimental spectra was to have P^1 exchange with P^3 or P^4 and to have P^2 exchange with P^3 or P^4 . Or, in other words, there was axial-equatorial exchange, but no axial-axial or equatorial-equatorial exchange of phosphorus atoms. The observed exchanges are the fundamental dynamic symmetry operations, but without revealing the mechanistic detail as to how they occur.

The authors felt that the complexity of this molecule is appropriate to demonstrate this kind of permutational analysis. Less complex molecules would not exhibit interesting exchange patterns, while more complex molecules might present too much of a computational problem. It should be noted that the development of two-dimensional NMR techniques after this paper was published provides direct instrumental access to revealing which nuclei are exchanging with which nuclei.

9 CHANGE OF SHAPE: POLYHEDRAL EXCHANGE

Four-coordinate nickel compounds often exist in solution as an equilibrium of 'square planar' and 'tetrahedral' isomers. (Generally the square planar complexes are not strictly D_{4h} and the tetrahedral complexes are not strictly T_d , but this distinction in the isomers is common in the literature and is useful. The quotation marks will be dropped in the discussion below.) The square planar isomers are diamagnetic while the tetrahedral isomers are paramagnetic. The paramagnetism in the tetrahedral isomers leads to very large shifts of NMR signals from their normal positions in diamagnetic isomers (or molecules in general). These very large shifts facilitate signal assignment in the slow exchange limit where the signal sets of the two isomers can be seen as two separate sets. It may stretch the definition somewhat, but the conversion between isomers could be called a dynamic symmetry operation. There have been detailed mechanistic proposals as to how the conversion occurs but they will not be discussed here. The components of these mechanisms could be more properly labeled as dynamic symmetry operations rather than the overall conversion.

Unfortunately in most instances the slow exchange limit is evidently below attainable temperatures and the only spectra obtained are the spectra averaged between isomers. The molecule, $[\text{MeP}(\text{Ph})_2]_2\text{NiBr}_2$, and related molecules, provide fortunate exceptions.¹⁰ At -65°C , the slow exchange spectrum demonstrates the very large chemical shifts that are induced by paramagnetism. For example, the signal from the *meta* protons in the tetrahedral isomer occurs at almost $\delta - 30$ ppm, while the corresponding signal for the square planar isomer occurs at the normal position for aromatic proton signals.

As the temperature is raised the separate signals begin to coalesce. Finally at 40°C , the averaged spectrum is obtained and with it, magnetic equivalence. The authors obtained 57 kJ mol^{-1} for $\Delta G^\ddagger$.

10 INTERCHANGE OF HYDRIDE HYDROGEN WITH MOLECULAR HYDROGEN AS LIGANDS

The dynamic symmetry operation here is the exchange back and forth, on the one hand, of two hydrogen atoms

Figure 2 The hydrogen/hydride equilibrium and the hydride region of the 250 MHz spectrum of the ion $[\text{ReH}_4(\text{CO})(\text{PMe}_2\text{Ph})_3]^+$. (Reproduced with permission from Crabtree, *Acc. Chem. Res.*, 1990, **23**, 95)

as a hydrogen molecule bound as one ligand, with the two hydrogen atoms bound separately as two separate hydride ligands, on the other hand.

This change between molecule and hydride manifests itself in several features of the variable temperature NMR spectra¹¹ of the ion $[\text{ReH}_4(\text{CO})(\text{PMe}_2\text{Ph})_3]^+$. The hydride region of the spectra is shown in Figure 2.

At 298 K, the entire hydride spectrum is just one broadened quartet with coupling to the three phosphorus atoms. The fast exchange limit and magnetic equivalence are being approached. As the temperature is lowered, this signal decoalesces quickly to give an AB quartet at high frequency (low field) and to produce an unresolved hump at lower frequency. At the lowest temperature, the low-frequency hump has decoalesced into a somewhat broadened AB quartet and a smaller hump. There must be two rate processes at work.

The higher temperature coalescence depends on the slowing down of the isomer equilibrium. The value of $\Delta G^\ddagger$ for the isomerization was found to be 49 kJ mol^{-1} at 213 K. The sharp, high frequency quartet is assigned to isomer (**6a**). In (**6a**) all the hydrogen atoms are bound to the metal as hydride hydrogens and, as a consequence, there is no further change in the spectrum of that isomer as the temperature is lowered. The spectrum of isomer (**6b**) continues to change as the temperature is lowered, which indicates that some

dynamic operation is coming into play. The final partial decoalescence of the spectrum of (**6b**) reflects the slowing down of the hydride/molecule interconversion within that isomer. The value of $\Delta G^\ddagger$ was found to be 41 kJ mol^{-1} . The interconversion has then played a role twice. This is one interesting example of the role of a dynamic process as occurring more than once in the same molecule. A number of examples have been published of multiple rotations, inversions, and combinations of these and other processes.

An interesting sidelight arises from the above experiment. Generally, 7- and 8-coordinate structures are *fluxional*. Interconversions between competing polyhedra are so rapid that the slow exchange spectrum is not attainable at the lowest temperatures that are available to NMR experiments. In the case discussed above, not only is the slow exchange spectrum of one such structure achieved, but also that of the other, competing polyhedron with a different coordination number. The 7-coordinate structure involves a molecule of hydrogen occupying only one coordination site. The 8-coordinate structure involves two hydrogen atoms, each occupying a coordination site.

11 INVERSION AND ISOMERIZATION IN METAL TRIS(DIKETONATES)

The octahedral complexes in which a metal is bonded to three β -diketone ligands provide instructive examples of the role of symmetry in NMR. ('Octahedral' is at best only approximately octahedral, but the term is used widely when discussing these complexes.) There is a very large amount of literature on this subject, but discussion here is focused on the complexes of (a) symmetrical diketones, $\text{RC}(\text{O})\text{CH}_2\text{C}(\text{O})\text{R}$, and (b) unsymmetrical diketones, $\text{RC}(\text{O})\text{CH}_2\text{C}(\text{O})\text{R}'$, and where a given complex has all three diketones as either (a) or (b).

The static symmetry of the symmetrical complexes (a) is D_3 (and not O_h). The three diketone chelate rings with the metal are all magnetically equivalent as entire rings. The complex is chiral and chirality will be apparent if diastereotopic nuclei or groups of nuclei are included. In practice it has been very useful for both R groups to be isopropyl. With this choice of ligand all the isopropyl groups are magnetically equivalent as entire groups, but the methyl groups within an isopropyl group are nonequivalent. In the slow exchange limit there will be two methyl doublets and the two will become one methyl doublet at the fast exchange limit. The dynamic symmetry operation is inversion of the complex.

The simplest visualization of the actual inversion mechanism is to assume a trigonal prism as the transition state. The transition state molecule could then either fall back into its original ground state geometry or into its enantiomer. While this mechanism has the virtue of simplicity, it is not generally accepted. Instead a dissociative mechanism is preferred. One end of one of the ligands breaks its bond to the metal such that the metal then becomes five-coordinate. The transition state geometry around the metal is supposed to be either a trigonal bipyramid or a square pyramid. The ligand that became unidentate in the transition state reattaches itself either to reform the original ground state or to form its enantiomer. These complexities admittedly stretch the concept of a single dynamic symmetry operation.

Complexes of type (b) can exist as *cis* or *trans* isomers. For the *cis* isomer there is one triangular face defined by three R groups. The vertices of the triangle opposite to this triangle are occupied by R' groups. The *cis* isomer has C_3 symmetry with the C_3 axis through the centers of the triangles above. As a consequence the three chelate rings are equivalent as entire rings. With R being isopropyl, the methyl groups are diastereotopic. The fast exchange spectrum of the methyl groups in an isopropyl group would consist of one doublet. The slow exchange spectrum would consist of two methyl doublets. Qualitatively the isopropyl spectrum of the *cis* isomer of a type (b) complex would be the same as for a type (a) complex.

On the other hand, the *trans* isomer of a type (b) complex has no static symmetry. The chelate rings are magnetically nonequivalent. With R being isopropyl, there would be six methyl doublets, two from each ring, at the slow exchange limit. However, the fast exchange limit would exhibit only one methyl doublet.

The dynamic symmetry operation for both *cis* and *trans* isomers is inversion. However, *cis* and *trans* isomers do not stand alone, each by itself. A *cis/trans* interconversion can also occur at the same time and can be considered as a dynamic symmetry operation. The discrete separation into racemization and isomerization events is considered to be difficult-to-impossible to achieve experimentally. The dissociation mechanism followed by arrangement into a five-coordinate geometry and a return to six-coordinate geometry could accomplish one or the other or both at once.

This complex situation with the tris(chelates) reflects the caveat stated in the Introduction. Straightforward dynamic NMR may reveal permutation patterns but cannot of itself supply mechanistic details.

Two studies of temperature-dependent NMR spectra particularly exemplify the discussion above. In both cases the metal was aluminum. The first¹² involved $\text{Al}(\text{Isopr}(\text{CO})\text{CH}(\text{CO})\text{Isopr})_3$ as type (a). The second¹³ study was with $\text{Al}(\text{PhCH}_2(\text{CO})\text{CH}(\text{CO})\text{Isopr})_3$ as a type (b) complex. (The formula for the isopropyl group is abbreviated as Isopr and that for the benzene ring as Ph.)

At 37°C the symmetrical complex, type (a), gives a slow exchange methyl spectrum that consists of two equal intensity doublets. At 120°C the two doublets coalesce and at 145°C the fast exchange spectrum as just one doublet is reached. At the lowest temperature isopropyl groups are equivalent as entire groups, but the diastereotopic methyl groups exhibit their nonequivalence as two doublets.

At 93°C the spectrum of the unsymmetrical complex shows 13 of the expected 16 methyl signals. At 139°C these doublets coalesce into one broad doublet. Finally, at 156°C, the one doublet sharpens. The fast exchange limit and magnetic equivalence obtain. There is no clear indication at intermediate temperatures that isomerization and inversion may be occurring as separate events in two well-defined temperature regions. The two dynamic symmetry operations must be very much entangled.

12 SLOW ROTATION AND POSSIBLE RING INVERSION IN A LANTHANUM COMPOUND

As a rule, complexes, molecules, and ions with central metal atoms with coordination number greater than six rearrange so

rapidly that the slow exchange limit and spectrum are not attainable. (They are said to be fluxional or *stereochemically nonrigid*.) Analysis indicates that with higher coordination numbers there are a number of competing polyhedra with nearly the same free energy. As a consequence there are one or more low-lying excited states that are readily accessible even at very low temperatures. As a result, magnetic equivalence persists in the variable temperature spectra of such compounds. However, macrocyclic ligands can confer enough rigidity to the structure of the complex species that slow exchange spectra become accessible. An example^{14a} is available with the lanthanum(III) complex ion (7) with 1,4,7,10-tetrakis(2-carbamoyl-ethyl)-1,4,7,10-tetraazacyclododecane (8).

Ring inversion and rotation around the amide bonds are both dynamic symmetry operations for this complex ion. (The authors do not specifically label the first process as ring inversion, but this seems to be one likely explanation of what is observed. This label is used throughout the rest of the discussion below.) The lanthanum atom is eight-coordinate. It is bound to the octadentate ligand through the four ring nitrogens and the oxygen atoms of the four amide groups. The lanthanum ion lies above the approximate plane of the macrocycle ring. There is a C_4 axis through the lanthanum atom and the center of the ring. Rotation around this axis is the static symmetry operation and it renders the four chelate rings equivalent as entire rings and the four amide groups equivalent as entire groups. The C_4 axis is the only static symmetry element. There is no symmetry plane. Much of the detail of the slow exchange structure of the complex in solution is suggested by the solid state structure of the complex.

The slow exchange disposition of the ring ethylene moieties is very important in rationalizing the slow exchange spectrum. Carbon-13 NMR shows that the carbon atoms within an ethylene moiety are nonequivalent. One carbon atom is closer to the lanthanum atom than is the other. For convenience in discussion, the carbon atoms within each ring ethylene group are described below as head- and tail-ends of the group. Also, the attached hydrogen atoms can be either axial or equatorial. Therefore, there are four environments for the ring ethylene hydrogen atoms. Also the head-and-tail arrangement of the carbon atoms alternates in going around the macrocycle ring. Hence, each of the ring nitrogens is chiral. These nitrogens are bound to four different atoms: (1) the lanthanum atom; (2) a carbamoyl-ethyl carbon atom; (3) a head carbon atom; and (4) a tail carbon atom. The hydrogen atoms are diastereotopic in both the methylene groups of the carbamoyl moieties. Also at the slow exchange limit, rotation around the amide bond in each amide group is slow.

The net result of all this is that the slow exchange spectrum for the protons should consist of two ABCD patterns, one

pattern for the ring hydrogens and one for the methylene hydrogens of the carbamoyl moiety, and finally an AB pattern for the amide nitrogen protons. Five different ^{13}C signals would be expected.

The experimental spectra in the slow exchange limit (0°C) confirmed these expectations, except that the protons attached to the amide nitrogen atom have a very small or even zero coupling constant to each other. As a consequence, two separate singlets were obtained for these protons rather than the expected AB quartet. Also the spectra for the ring hydrogens and for the hydrogens of the methylene groups of the carbamoyl moiety are so complicated, and with considerable overlap, that it is not easily possible to discern clearly two ABCD patterns. However, the authors did assign parts of these signals to specific protons or groups of protons.

A complete proton spectrum in the fast exchange limit was not given. However, the two amide proton singlets collapsed into one singlet as these protons became magnetically equivalent at 92°C . Signal shape analysis showed that the activation energy for rotation around the amide bond is 69 kJ mol^{-1} .

The ring carbon atoms coalesced in the ^{13}C spectrum at 29°C and a barrier of 60 kJ mol^{-1} was obtained. The ring carbons become magnetically equivalent, the head-to-tail difference is lost, and with it the chirality of the ring nitrogens. It would be expected that the loss of the head-to-tail difference and the axial/equatorial distinction between ring protons would lead to a collapse into a singlet for those protons at the fast exchange limit. If on the other hand some dynamic operation other than ring inversion is occurring, and the axial/equatorial difference is preserved, a doublet or possibly an AB quartet would be observed. The loss of chirality should alter the low temperature ABCD pattern of the methylene protons of the carbamoyl moiety to an AA' BB' pattern since these protons would no longer be diastereotopic in the chemical shift sense.

NMR studies of the complexes with paramagnetic lanthanides would be interesting, since chemical shift differences would be enhanced and first-order NMR patterns could result with easy analysis of these patterns. The variable temperature spectra of the paramagnetic complexes of the related tetraacetate macrocycle have been reported.^{14b} With this macrocycle the situation is further complicated by the coexistence of two isomers of the complexes. However, the expanded chemical shift scales that are obtained tend to compensate for this complication.

13 RING WHIZZING

Cyclopentadiene rings can be bonded to metals in either of two modes. In one mode, the bonding (pentahapto bonding symbolized as η^5 bonding) is to the ring as a whole. In this mode the metal is bonded to the ring as a whole rather than being bonded to one specific carbon atom in the ring (monohapto bonding or η^1). For the pentahapto situation, the protons of the ring are all magnetically equivalent as are the carbon atoms. The monohapto mode gives three sets of nuclei that are not equivalent between the sets. The proton attached to the bonded carbon atom is by itself one set (H_a , shown as A in Figure 3). The two protons in the once removed positions (H_b , shown as B) are the second set and are magnetically equivalent

Figure 3 Exchange patterns in a cyclopentadiene ring

to each other. The remaining two protons (H_c , shown as C) form the third set and are equivalent to each other.

In effect, the static symmetry of the monohapto-bonded ring is a symmetry plane perpendicular to the ring, including the bonding site and passing between the carbon atoms of each of the pairs of carbon atoms. The dynamic symmetry operation is the changing of site of the bonded-to-metal carbon atom. This operation is commonly called *ring whizzing*.

From the pentahapto-bonded ring, the proton resonance should just be a sharp singlet at all temperatures. In the fast exchange limit for the protons of the monohapto-bonded ring, rapid change in the bonding site should also lead to a singlet. While in the slow exchange limit (slow change in the bonding site), the magnetically equivalent sets should give signals from each set. In practice the lone proton gives a singlet and the remaining four protons give an AA'BB' pattern.

The ring complex $(\eta^5\text{-C}_5\text{H}_5)(\eta^1\text{-C}_5\text{H}_5)\text{Fe}(\text{CO})_2$ has a ring of each kind in the molecule and demonstrates this behavior.¹⁵ The results of a variable temperature study are shown in Figure 4.

At 30°C the fast exchange limit is achieved. The whole proton spectrum consists of just two singlets. The signal at lower frequency is from the pentahapto-bonded ring and the one at higher frequency the signal averaged over all the protons of the monohapto-bonded ring.

The signals at the slow exchange limit are assigned as follows, going from high frequency to low frequency. The multiplet at highest frequency is assigned to the two H_b and the two H_c protons as the expected AA'BB' pattern. The lower half of this pattern is assigned to the H_b protons and the other half to the H_c protons. This particular part of the overall assignment of proton signals is absolutely crucial to the rationalization of the variable temperature spectra as given below. The singlet at

Figure 4 Ring whizzing and its effect on the proton spectrum of $(\eta^5\text{-C}_5\text{H}_5)(\eta^1\text{-C}_5\text{H}_5)\text{Fe}(\text{CO})_2$. (Reproduced with permission from Cotton, *Acc. Chem. Res.*, 1968, 1, 257)

about 5.6 ppm is from the pentahapto ring protons and remains unaltered throughout the temperature changes. The singlet at about 6.5 ppm is from the lone hydrogen that is attached to the bonding carbon atom.

As the temperature is raised all the signals from the bonded ring broaden, but the high frequency half of the AA'BB' set broadens more rapidly than the lower frequency half. This shows that exchange of the H_b protons is occurring more rapidly than of the H_c protons. This, in turn, provides the decisive evidence as to how the bonding site shifts around the ring as ring whizzing (or, more elegantly, metal migration around the ring) takes place. The two plausible mechanisms are (1) a 1,2-shift or (2) a 1,3-shift. The exchange (or permutation) patterns that result are shown in Figure 3.

With the 1,2-shift, both H_bs are exchanged in each migration of the iron atom, but only one H_c. For one metal migration, the H_b exchange is twice as fast and the higher-frequency wing of the AA' BB' pattern would be expected to broaden twice as fast as the lower-frequency wing when the temperature is increased. On the other hand, with a 1,3-shift, the situation is reversed and the lower-frequency wing should broaden first.

This analysis, overall, is impressive and seems to demonstrate that not only in a general way is ring whizzing the dynamic symmetry operation, but in more detail that the 1,2-shift is the dynamic symmetry operation. A ¹³C temperature study could make the analysis even more impressive.

14 BRIDGE/TERMINAL EXCHANGE AND ISOMERISM IN A BRIDGED IRON COMPOUND

The compound under discussion could exist as any one or several of the isomers shown below.

By a combination of infrared and NMR spectroscopy and elegant reasoning, the authors¹⁶ were able to eliminate all possibilities except isomers (9) and (14). Isomer (9) has C_{2v} static symmetry with one CNCH₃ group above the plane of the paper and the other below that plane. (The above-the-plane, below-the-plane detail is omitted from the structural formulas.) There is a C₂ axis through the nitrogen atoms. (The

Figure 5 Variable temperature proton spectra of the compound (η⁵-C₅H₅)₂Fe₂(CO)₂(CNCH₃)₂. [Reprinted with permission from Adams and Cotton, *J. Am. Chem. Soc.*, **95**, 6589. Copyright (1973) American Chemical Society]

dispositions of the CH₃ groups is represented in an arbitrary fashion and does not affect the symmetry.) On the other hand, isomer (12) has no static symmetry.

The slow exchange proton spectrum at 26°C (Figure 5) reflects these symmetry considerations. The static symmetry of isomer (9) renders the cyclopentadienyl groups magnetically equivalent within the pair of these groups and does the same for the methyl groups. The signals at 5.33 and 6.37 ppm and with relative intensity 5:3 are assigned to the cyclopentadienyl and methyl groups of isomer (9). The set of signals at 5.38, 5.47, 6.23, and 7.48 ppm with relative intensity within the set of 5:5:3:3 are assigned to one cyclopentadienyl group, to the other cyclopentadienyl group, to the bridging CNCH₃ group, and to the terminal CNCH₃ group, respectively, all for isomer (12).

The signals for isomer (9) remain relatively sharp as the temperature is raised at first. Meanwhile the signals from isomer (12) are noticeably broadened even at 45°C. At about 60°C and higher the isomer (9) signals also broaden. At 97°C all the cyclopentadienyl signals coalesce into one sharp singlet and fast exchange is approached. The methyl signals have coalesced, but due to large chemical shift differences have not yet emerged from the baseline.

Two dynamic processes (or symmetry operations) must be taking place. The first, at lower temperature, is the exchange of bridge and terminal cyclopentadienyl and CNCH₃ groups within isomer (12). The second process, at higher temperature, must be that the isomerization process itself becomes rapid.

15 CONCLUSIONS

Two closely related aspects of NMR, magnetic equivalence and dynamic NMR, have been foci of investigations at least

since the Phillips paper¹ on dimethylformamide. Magnetic equivalence in the slow exchange limit can often be analyzed to reveal the static symmetry of a chemical species or at least to limit the choices of static symmetry. Structural details of species in solution (or even the gas phase) are deducible from static symmetry. Structural determination in whatever phase is always an important goal in chemistry. Structural determination by NMR is now in an advanced state of development.

1. Dynamic NMR can provide two sorts of information. Signal shape analysis can yield rate data in a range of rates that are much too fast to be accessible by classical rate experiments. Signal shape analysis is also now in an advanced state of development.
2. Dynamic NMR can provide information that bears on the mechanisms for various intramolecular motions and rearrangements. Mechanisms are always dear to the hearts of chemists. Mechanism elucidation, aided by dynamic NMR, has been successful in many cases. Nevertheless, this is a *relatively* undeveloped approach to the study of mechanisms.

It seems likely that continued development will depend heavily on an expanding combination of two endeavors. The first of these is the use of two-dimensional NMR (and perhaps, other NMR instrumental techniques) to identify mutually exchanging nuclei. The second is the application of the theory of permutation groups.

1 INTRODUCTION

Efficient algorithms for computing the discrete Fourier transform (DFT) served as one of the enabling technologies behind the development of modern NMR spectroscopy.¹ While use of the fast Fourier transform (FFT) was widespread in science and engineering in the 1960s, it was nevertheless a fairly audacious proposal in 1965 to use the FFT to analyze time domain data as an alternative to conventional field or frequency swept experiments, since the marriage of a computer capable of performing the FFT to an NMR spectrometer had yet to be consummated. The implications turned out to be profound, of course, opening the way to the development of multidimensional NMR and magnetic resonance imaging. Yet while providing a crucial capability, the DFT is not without inherent limitations, some of which can be avoided by the use of alternative methods that would have been impractical in 1965, or even as recently as 1990.

2 LIMITATIONS OF THE DFT

The reasons for using the DFT are compelling, beyond even the efficiency of FFT algorithms. Among them are the linearity of the DFT (which simplifies quantification and error analysis and also permits applications such as difference spectroscopy) and the full weight of the theory behind the continuous Fourier transform.² A time series can be characterized as a finite sum of periodic functions, given by the inverse DFT

$$d_k = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} f_n e^{2\pi i k n / N} \quad (1)$$

where d_k is the value of the time series at time $k \Delta T$, ΔT is the interval between samples, f_n is the coefficient of the Fourier

component with frequency $n/N \Delta T$, and N is the number of Fourier components (which is equal to the number of samples in the time series). The Fourier coefficients are computed by the forward DFT

$$f_n = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} d_k e^{-2\pi i k n / N} \quad (2)$$

Differences between the DFT and the continuous Fourier transform result from sampling and truncation, in both time and frequency. Sampling in the time domain can introduce artifacts in the spectrum, in which components with frequencies greater than $1/\Delta T$ appear at lower frequencies (aliasing). Truncation in the time domain introduces spurious spread of the components in the spectrum (leakage). Characterization of a time series beyond the sampled interval by means of Fourier coefficients computed from the interval (which is equivalent to estimating the spectrum with a digital resolution higher than $1/N \Delta T$) is correct only for periodic time series, since each Fourier component in equation (1) satisfies $e^{2\pi i k n / N} = e^{2\pi i (k+N)n / N}$.

Another difficulty associated with the DFT stems from the relationship between the number of data samples and the digital frequency resolution. The term digital frequency resolution is used to refer to the frequency difference between adjacent points in a discrete spectral estimate, and it should be distinguished from the resolution of the spectral estimate, which is a measure of the ability of a spectral estimate to distinguish between closely spaced frequency components. The digital resolution places a lower bound on the resolution of a spectral estimate. The spacing between points in the frequency domain is given by $1/N \Delta T$; therefore, to achieve high digital frequency resolution it is desirable to collect as long a data record as possible. In pulsed NMR experiments, however, the signal of interest usually diminishes with time. Thus collecting long data records to improve resolution rapidly leads to diminishing returns by degrading the signal-to-noise ratio (S/N) of the resulting spectrum. A technique for overcoming this degradation is to collect data for a short period of time and then append zeroes to the end (zero filling). This process also introduces discontinuities into the time series, resulting in leakage. The leakage can be severe if the signal of interest has not decayed sufficiently before the end of the sampled interval. Weighting functions (also referred to as apodization, window, or taper functions) can be applied to the time data, to minimize the extent of leakage by reducing the intensity of the signal near the end of the sampled interval, although this generally incurs an accompanying loss of resolution due to broadening of the spectral components. A virtual zoo of weighting functions exists, each function fulfilling a different goal (leakage reduction, resolution enhancement, sensitivity enhancement) or striking a compromise between various goals.³ In particular the matched filter (which mimics the decay of the FID envelope), because of its theoretical properties, has long been employed to enhance sensitivity.⁴

One way to extend a time series in a more intelligent fashion than appending zeroes, is to extrapolate using linear prediction. Linear prediction is based on a model in which each value of a time series is assumed to be a linear combination of the preceding values. However, linear prediction is not

always appropriate. It is strictly correct only for exponentially decaying sinusoids, it requires a relatively high S/N, and it is only applicable to time series that have been sampled at uniform intervals. (See *Fourier Transform and Linear Prediction Methods*.)

3 SPECTRUM ANALYSIS AS AN INVERSE PROBLEM

A more general approach, that avoids the limitations of the DFT and linear prediction, treats spectrum analysis of a time series as an inverse problem. Inverse problems are those in which the properties of interest can only be viewed indirectly. A famous example is Plato's allegory of the cave,⁵ in which the problem is to infer the characteristics of an object from the shadows in the firelight it casts on the walls of a cave. In NMR spectrum analysis, the inverse problem can be stated as that of recovering the spectrum f_n of an ensemble of spins, when the only observations we have are the FID at various times (d_k), contaminated by noise (ϵ_k):

$$\hat{d}_k = d_k + \epsilon_k \quad (3)$$

We can approach this inverse problem by placing restrictions on the possible solutions f_n . The first restriction comes from the obvious requirement that f_n must be consistent with the experimental observations. The agreement can be quantified through the use of a constraint statistic that measures how well the reconstructed spectrum agrees with the available data. The statistic is determined by comparing a 'mock' FID, given by the inverse DFT of the reconstructed spectrum, with the actual data. When the noise and experimental error in the measured data are normally distributed, an appropriate statistic is the (unweighted) χ^2 statistic,

$$\chi^2 = \sum_{k=0}^{M-1} |m_k - \hat{d}_k|^2 \quad (4)$$

where M is the number of data samples collected, and m_k is the mock FID. Other forms of the constraint statistic, C , are possible, but χ^2 is the one generally used, because of its simplicity and the difficulty in justifying any other distribution of errors in the data. (A weighted χ^2 statistic can also be used, for example, if there is good reason to believe that some of the data points are more subject to error than others.) Whatever the form of C , the constraint that the reconstructed spectrum must be consistent with the measured data takes the form

$$C \leq C_0 \quad (5)$$

where C_0 is an upper bound on the allowed error. Given a prior estimate of the amount of noise in the data, C_0 should be comparable to the root-mean-square (RMS) noise level.

4 SOLVING THE INVERSE PROBLEM USING MAXIMUM ENTROPY RECONSTRUCTION

The constraint statistic alone does not provide enough of a restriction on the possible reconstructions to be of much use.

In fact, any mock FID that matches the experimental FID to within C_0 for the first M points will satisfy the constraint. If we are to improve over the DFT, we need some additional criteria for regularizing the reconstructed spectrum, that will effectively constrain the values of the mock FID beyond M . One such criterion is the maximum entropy principle, which says that a reasonable reconstruction should add no new information beyond that contained in the experimental data. The principle originated in the work of Claude Shannon on the information-carrying capacity of circuits,⁶ where he showed that the entropy of a probability distribution p , defined by

$$S(p) = - \sum_n p_n \log p_n \quad (6)$$

is a measure of the lack of information. There is a formal link between Shannon's entropy and the statistical entropy of an ensemble, and this link can be used to provide a constraint on possible spectrum reconstructions. On a more pragmatic level, the maximum entropy principle can be viewed simply as a means of obtaining a smooth, bounded reconstruction. The use of the maximum entropy principle to regularize the possible solutions to the spectrum analysis inverse problem is called maximum entropy (MaxEnt) reconstruction. [Maximum entropy reconstruction should be distinguished from the maximum entropy method (MEM) introduced by Burg,⁷ which is more closely related to linear prediction.] Entropy is not unique as a regularizer, however, and there are other functionals that have similar properties.⁸

An important distinction between MaxEnt reconstruction and methods of spectrum analysis (such as those based on linear prediction) that implicitly assume Lorentzian lineshapes, is that MaxEnt reconstruction per se makes no assumptions about the signal to be recovered. Yet it is flexible enough to allow prior information to be incorporated into the reconstruction. A particularly simple means for incorporating prior knowledge is through a convolution kernel. Typical kernels might include exponential decay at some known rate, or J modulation at a known frequency. The reconstruction then yields the *deconvolved* spectrum having the highest entropy.

5 NUMERICAL ALGORITHM

The maximum entropy principle provides a formal basis for reconstructing the spectrum f_n , but some additional details must be addressed in order to apply MaxEnt reconstruction to NMR data. For modern NMR experiments, we need to be able to reconstruct complex spectra containing both positive and negative components. The Shannon formula [equation (6)] clearly does not apply to complex-valued spectra. A more suitable approach is to find the spectrum corresponding to a maximum entropy ensemble of spin- $\frac{1}{2}$ particles.⁹ The resulting formula is

$$S(f) = - \sum_{n=0}^{N-1} \frac{|f_n|}{def} \log \left(\frac{|f_n|/def + \sqrt{4 + |f_n|^2/def^2}}{2} \right) - \sqrt{4 + |f_n|^2/def^2} \quad (7)$$

where def is a scale factor. The maximum entropy distribution prescribes the value of def (it depends on the spectrometer

response and the total number of spins in the sample). However, it is more convenient to treat def as an adjustable parameter.

The next detail that we are faced with is how to solve the constrained optimization problem, that is, the problem of maximizing $S(f)$ subject to the constraint that $C \leq C_0$. An equivalent unconstrained optimization problem is to maximize the objective function

$$Q = S - \lambda C \quad (8)$$

where λ is a Lagrange multiplier. The solution we seek corresponds to a critical point of Q , i.e., a point where $\nabla Q = 0$. In the general case there is no analytic solution to this problem, and we are forced to seek numerical solutions. For many problems of this type, a numerical search using the gradient of the objective function (steepest ascent or conjugate gradients) is a reasonably efficient method for finding the critical point. Unfortunately, an objective function constructed from two such dissimilar functionals as the χ^2 statistic and the entropy is quite difficult to maximize. Practical solution of the general MaxEnt reconstruction problem requires a fairly complex optimizer, and the most efficient algorithms require of the order of 100 (or more) times the computational effort of the FFT.

Since the entropy [given by equation (7)] and the constraint statistic [equation (4)] are both everywhere convex, there is a unique, global solution to the constrained optimization problem. Furthermore, this maximum satisfies $C = C_0$ provided that the trivial solution $f_n = 0$ does not also satisfy the constraint.

There have been several algorithms published for computing MaxEnt reconstructions. A particularly robust and efficient algorithm was described by Skilling and Bryan.¹⁰ This method uses multiple search directions and a variable metric to determine the size of the step at each iteration. We describe here a variant we have found useful in our laboratory.

The algorithm begins with a flat trial spectrum equal to zero everywhere. At each iteration, a mock FID is computed from the current value of the trial spectrum. In the general case this involves inverse Fourier transformation and multiplication by a decay kernel, which is specified by the user as an input parameter. A decay does not need to be applied, but when it is, the reconstructed spectrum is an approximation of what would have been observed had the decay not been present. The first M points of the N point mock FID are used to compute the value of C , according to equation (4). The algorithm constructs a small set of direction vectors, and computes a quadratic approximation to the entropy in the subspace spanned by these vectors. Since the constraint is itself quadratic, it is possible to maximize analytically the entropy approximation subject to the constraint in this subspace. This results in the trial spectrum for the next iteration.

The quadratic approximation to the entropy is accurate only for small step sizes, so when the value of C for the mock FID is far from the desired value C_0 , it is better to solve the analytic maximization using a constraint value C' , intermediate between C_0 and the current value of C , rather than attempt one large step. Consequently the algorithm proceeds in two phases. In the first phase, C is larger than C_0 and the algorithm attempts to lower C . In the second phase, C_0 has been attained and the algorithm seeks to maximize the entropy.

This approach could be based on direction vectors that include ∇S , the gradient of the entropy (with respect to f). The problem is that the gradient can be dominated by small values of f , and the algorithm would spend more time adjusting values that are close to zero than adjusting signal peaks. The key insight of Skilling and Bryan was that the introduction of an 'entropy metric' produces an algorithm that more evenly weights the contributions of large and small values of the spectrum. Using the entropy metric amounts to replacing ∇S and ∇C (the gradient of the constraint with respect to the trial spectrum) with $\mathbf{H}^{-1}\nabla S$ and $\mathbf{H}^{-1}\nabla C$, where $\mathbf{H}$ is $-\nabla^2 S$, the negative of the Hessian (the matrix of second derivatives) of S . The matrix $\mathbf{H}$ is nearly diagonal, so its inverse is easy to compute. The search directions used during the first phase of the algorithm are:

$$\begin{aligned} &\nabla C \\ &\mathbf{H}^{-1}\nabla C \\ &\mathbf{H}^{-1}\nabla Q \\ &\mathbf{H}^{-1}(\nabla^2 C)\mathbf{H}^{-1}\nabla Q \\ &Q = S - \lambda C \end{aligned} \quad (9)$$

and λ is set to $|\nabla S|/|\nabla C|$. During the second phase, the second search direction is replaced by ∇Q . In the original algorithm of Skilling and Bryan, neither ∇C nor ∇Q are used as search directions. We found that including them speeds convergence. The major effort in computing these vectors stems from four discrete Fourier transformations (two each to compute ∇C and to apply $\nabla^2 C$) and multiplication by $\mathbf{H}^{-1}$.

With these direction vectors, a quadratic model for the entropy and the constraint can be constructed using a second-order Taylor expansion about the trial spectrum. A spectrum f' in the subspace spanned by the direction vectors can be represented by a vector of length four, $\bar{a}$; the correspondence is given by

$$f' = a_1 v_1 + a_2 v_2 + a_3 v_3 + a_4 v_4 + f_0 \quad (10)$$

where v_1 through v_4 are the direction vectors and f_0 is the current trial spectrum. The quadratic approximations then become

$$S(\bar{a}) \approx S(f_0) + \bar{B} \cdot \bar{a} + \frac{1}{2} \bar{a} \cdot \mathbf{M} \cdot \bar{a} \quad (11a)$$

and

$$C(\bar{a}) \approx C(f_0) + \bar{G} \cdot \bar{a} + \frac{1}{2} \bar{a} \cdot \mathbf{N} \cdot \bar{a} \quad (11b)$$

where vectors $\bar{B}$ and $\bar{G}$ are inner products of ∇C and ∇S with the direction vectors

$$\bar{B}_i = \nabla S \cdot v_i \quad (12a)$$

$$\bar{G}_i = \nabla C \cdot v_i \quad (12b)$$

Similarly, the 4×4 matrices $\mathbf{M}$ and $\mathbf{N}$ are the inner products of $\nabla^2 S$ and $\nabla^2 C$ with the direction vectors:

$$M_{ij} = v_i \cdot \nabla^2 S \cdot v_j \quad (13a)$$

$$N_{ij} = v_i \cdot \nabla^2 C \cdot v_j \quad (13b)$$

Computing these values requires several more Fourier transformations and large matrix products. The Lagrange condition $\nabla S - \lambda \nabla C = 0$ for the maximum of the objective function in the subspace becomes

$$(\bar{B} + \mathbf{M} \cdot \bar{a}) - \lambda(\bar{G} + \mathbf{N} \cdot \bar{a}) = \bar{0} \quad (14)$$

By a suitable change of coordinates in the subspace it is possible to simplify this equation by simultaneously diagonalizing $\mathbf{M}$ and $\mathbf{N}$. The solution then is given by

$$a_i = \frac{B_i - \lambda G_i}{\lambda N_{ii} - M_{ii}} \quad (15)$$

λ can be found by using a binary search to determine the value for which $C(\bar{a})$ equals the target value C' .

Convergence criteria for determining when the trial spectrum is sufficiently close to the MaxEnt reconstruction derive from the Lagrange condition and the requirement that $C \approx C_0$. The Lagrange condition implies that ∇C and ∇S are parallel, so convergence can be monitored by computing the value

$$Test = \left| \frac{\nabla S}{|\nabla S|} - \frac{\nabla C}{|\nabla C|} \right| \quad (16)$$

The algorithm terminates when $C \approx C_0$ and $Test \ll 1$. In practice, we stop the algorithm when $Test < 10^{-3}$, or when a preset maximum number of iterations has been executed.

The value of C_0 can be estimated from the data by examining a portion of an FID that is essentially free of signal, or alternatively, by examining a signal-free region of the DFT spectrum. For MaxEnt reconstructions, C_0 should generally be somewhat larger than the estimate of the RMS noise level. Very large values of C_0 result in overly smooth reconstructions in which weaker components are washed out.

The other adjustable parameter, def , is rather more difficult to prescribe. def represents the scale at which the nonlinear effects of MaxEnt reconstruction become significant. A large value of def results in nearly linear reconstructions. When def is large and C_0 is zero, the resulting reconstruction is essentially the same as the DFT of the zero-filled FID. However, very low values of def can give rise to spurious artifacts. As a rule of thumb, we use values of def somewhat lower than the noise level. Fortunately, the results are not overly sensitive to the choice of def . We know of no algorithmic procedure for determining the best value.

6 ANALYTIC SOLUTION

While numerical solution is required in the general case, there is a special case of MaxEnt reconstruction that has an analytical solution. Though unrealistic in several respects, examination of this special case can give some insights into how MaxEnt reconstruction works. When N (the number of points in the reconstructed spectrum) is equal to M (the number of experimental data points), and when the relationship between the trial spectrum and the mock FID is given simply by the inverse Fourier transform (i.e. we are not trying to deconvolve a decay), the solution can be found analytically.

Parseval's theorem, which states that the sum of the squared magnitudes of a vector is equal to the sum of the squared magnitudes of its Fourier coefficients, permits the constraint statistic to be computed in the frequency domain. Under these circumstances the Lagrange condition becomes

$$0 = \nabla Q = \nabla S - 2\lambda(f - F) \quad (17)$$

where F is the DFT of the data $\hat{d}$. The solution is given by

$$|f_n| = \delta_\lambda^{-1}(|F_n|) \quad (18a)$$

$$\text{phase}(f_n) = \text{phase}(F_n) \quad (18b)$$

where δ_λ is the function

$$\delta_\lambda(x) = x - s'(x)/2\lambda \quad (19)$$

and $s(x)$ is the contribution of a spectral component with magnitude x to the overall entropy S [see equation (7)]. This result corresponds to a nonlinear transformation, applied point by point to the DFT of the time domain data. The transformation depends on the value of λ , and has the effect of scaling every point in the spectrum down, but points closer to the baseline are scaled down more than points far above the baseline. Figure 1 illustrates $\delta_\lambda^{-1}(x)$ for various values of λ . As λ increases, the relative weight given to the constraint term in the objective function increases, and the transformation becomes more nearly linear.

This helps to explain the characteristic of MaxEnt reconstructions that noise near the baseline is suppressed more than noise away from the baseline (for example, superimposed on a broad peak). A further point to note is that there is a very important distinction between S/N and sensitivity. Sensitivity is the ability to distinguish signal from noise. Applying the same transformation to both the signal and the noise cannot improve this ability, since peaks that are comparable in height to the noise level will be reduced by the same amount as the noise. The ratio between the highest signal peaks and the noise

Figure 1 The nonlinear transformation $\delta_\lambda^{-1}(x)$ applied to the DFT spectrum that results in the MaxEnt reconstruction when $N = M$, for various values of the Lagrange multiplier λ .

may increase, but small peaks will be just as difficult to distinguish as before. For linear operations (such as apodization), an improvement in S/N necessarily implies an improvement in sensitivity; for nonlinear operations (such as MaxEnt reconstruction) this is not so. In this special case, gains in S/N in the MaxEnt reconstruction are purely cosmetic. In the more general case, for example when an approximately known decay is deconvolved from the reconstructed spectrum, there may be real sensitivity gains. However, a prudent investigator will always question whether gains in S/N really correspond to gains in sensitivity.¹¹

7 EXAMPLE APPLICATIONS

Armed with an efficient optimizer, the Cambridge Maximum Entropy group and their collaborators performed the earliest applications of MaxEnt reconstruction to NMR.¹² Properties of MaxEnt reconstruction depend on both the data and the parameters of the reconstruction, such as the decay kernel, and so are best illustrated by examples using typical NMR data. In addition to providing a concrete means of exploring the use of MaxEnt reconstruction for improving resolution or enhancing sensitivity, they provide a means of comparing the performance of alternate methods.

7.1 One-Dimensional

7.1.1 Resolution

Figure 2 illustrates the methyl and aliphatic region of spectra obtained for a sample of 20 mM L-Ala-L-Pro in D₂O at pD 6.0 and 25°C. Data consisting of 1024 complex points were collected at 400 MHz on a JEOL GX-400 spectrometer. Shown are the zero-filled (to 8192 points) DFT spectrum without (a) and with (b) windowing (60°-shifted sine-bell). Figure 2(c) is the DFT spectrum obtained by extrapolating from 1024 points to 8192 with linear prediction, using a filter order of 60 and reflecting roots of the characteristic polynomial that fall outside the unit circle to the inside. Figure 2(d) illustrates the MaxEnt reconstruction, computed using 1.0 for C_0 and 0.1 for def . All parts of Figure 2 are plotted using the same scale. The region near the methyl peaks (around 1.55 ppm, arising from both the *cis* and *trans* forms of the peptide bond) shows the artifacts due to truncation. Windowing the FID ameliorates the artifacts, at the expense of lower resolution due to broadening. More aggressive resolution enhancement (for example a 30°-shifted sine-bell) improves the resolution at the expense of more pronounced negative 'wings' surrounding the methyl peaks. Extrapolation by linear prediction [Figure 2(c)] dampens the artifacts somewhat; further reduction could be obtained by windowing the extrapolated FID. The MaxEnt reconstruction [Figure 2(d)] is virtually free of artifacts and has narrow lines; further line narrowing could be achieved by deconvolving the natural linewidth.

7.1.2 Signal-To-Noise Ratio

Figure 3 illustrates gains in S/N that can be achieved using MaxEnt reconstruction. Figure 3(a) contains the aliphatic

Figure 2 Aliphatic region of the ¹H spectrum of L-Ala-L-Pro, from 1024-point data: (a) zero filled to 8192 and Fourier transformed; (b) zero filled, apodized using a 60°-shifted sine-bell and Fourier transformed; (c) extrapolated to 8192 points using linear prediction and Fourier transformed; (d) MaxEnt reconstruction

region of the DFT spectrum for a sample of 0.1% ethylbenzene in deuteriochloroform, using a single 90° observe pulse; 1024 complex points were zero-filled to 4096 and windowed using a 60°-shifted sine-bell prior to Fourier transformation. Figure 3(b) shows the DFT spectrum of data collected using a 7° observe pulse, and processed as in Figure 3(a). Figure 3(c) shows the MaxEnt reconstruction obtained using 2.8 for C_0 and 0.01 for def ; no decay was deconvolved. Although striking, the improvement in S/N does not necessarily correspond to a real gain in sensitivity, as discussed earlier. Note that the multiplet structure of the peak near 3.25 ppm is not much more evident in (c) than in (b).

7.1.3 Robustness

A characteristic of MaxEnt reconstruction that distinguishes it from parametric methods, such as linear prediction, is that it makes no implicit assumptions about the nature of the data (although using MaxEnt reconstruction to perform deconvolution does presume the convolution kernel to be correct). Linear prediction, however, is strictly correct only for exponentially decaying sinusoids. MaxEnt is thus less

Figure 3 Aliphatic region of the ^1H spectrum of ethylbenzene: (a) obtained using a 90° observe pulse; (b) obtained using a 7° observe pulse followed by 60° -shifted sine-bell apodization, zero filling, and Fourier transformation; (c) obtained using a 7° observe pulse followed by MaxEnt reconstruction

susceptible to bias when the signal has unusual characteristics such as markedly nonexponential decay, when the S/N is low, or when the data have been corrupted. It is quite common for points at the beginning of a FID to be corrupted, which can result in distorted baselines. In these circumstances, backwards linear prediction can be used to correct the corrupted points. However, if the corrupted data points are in the middle of a FID, or distributed in some unusual fashion throughout the FID, linear prediction is less useful. MaxEnt reconstruction, however, does not require the data to be sampled at uniformly spaced intervals, and so can be applied quite easily to data that are corrupted in an irregular fashion. It is our own sad experience that points in the indirect dimensions of long multidimensional experiments are occasionally contaminated by intermittent instrument failure or environmental influences. Maximum entropy reconstruction provides a means of recovering useful spectra from such data.

To demonstrate the possibilities, we consider a contrived example, constructed by manually corrupting the one-dimensional FID used to generate Figure 3(a). The complex 1024-point FID was corrupted by setting to zero the real and imaginary parts of the points from 350 to 359 and 750 to 759. Figure 4(a) shows the DFT spectrum of the corrupted FID, zero-filled to 4096 points. Figure 4(b) and (c) are 4096-point MaxEnt reconstructions, using 1.0 for C_0 and 0.1 for def , and without deconvolving a decay. In Figure 4(b) all 1024 points of the FID were included in the computation of χ^2 , while in Figure 4(c) the corrupted points were left out. Figure 4(b) illustrates that MaxEnt reconstruction is much more robust to

Figure 4 Spectra computed from data corrupted at two interior stretches of the FID using: (a) Fourier transformation, (b) MaxEnt reconstruction utilizing the entire data set, and (c) MaxEnt reconstruction excluding the corrupted data points

data contamination than the DFT. Figure 4(c) shows the flexibility of MaxEnt reconstruction for treating data corrupted at arbitrary locations when the points of corruption are known.

7.2 Multidimensional

Maximum entropy reconstruction can also be applied to multidimensional data, and it is here that the ability to obtain high-resolution spectra from short data records offers the most significant benefits. Since the data collection time increases linearly with the amount of data collected in indirect dimensions of a multidimensional data set, resolution in these dimensions is often limited by practical considerations of the amount of experiment time available. An advantage of MaxEnt reconstruction over linear prediction for ameliorating those constraints is that the data samples need not be collected at uniform intervals, allowing data collection to be tailored to the type of experiment, sampling more frequently when the S/N is high and hence making more efficient use of available measuring time.

There are a number of ways MaxEnt reconstruction can be extended to multiple dimensions. The most general is simply to compute the entropy of the entire spectrum. As a practical matter, however, this can present a formidable computational challenge for large data sets, since each iteration of the reconstruction algorithm requires several transformations from the time to the frequency domain (and back). An alternative that is far less demanding is to apply MaxEnt reconstruction to each FID in one dimension independently. With this approach, MaxEnt reconstructions of large multidimensional data sets

can be performed efficiently on typical workstations. With a small modification to the algorithm, this approach using a series of one-dimensional reconstructions yields results that are nearly equivalent to the more general multidimensional reconstruction.

In one-dimensional MaxEnt reconstruction, one seeks the local maximum of the objective function for which $C = C_0$. This occurs for a specific value of λ . When computing MaxEnt reconstruction for the rows of a multidimensional data set, normal variations in the noise and the signal can result in different values of λ for each row. The consequences of this variation are often insignificant, but they can be important if they are large enough to perturb the lineshapes, or if quantification of the reconstructed spectrum is performed. Since the nonlinearity of MaxEnt reconstruction depends on the relative weights applied to the entropy and the constraint statistic, it is important to ensure that the same weight (value of λ) applies to each row. This is relatively easy to accomplish by choosing a typical row, estimating the noise, and computing a normal one-dimensional MaxEnt reconstruction. For the multidimensional data set, each row is then reconstructed using the value of λ obtained from the reconstruction of the trial row, instead of iterating to achieve $C = C_0$.

While the resolution of a spectrum determined by MaxEnt reconstruction is mainly determined by the time of the last data sample (as for the DFT), higher sensitivity for the same number of measurements can be achieved by tailoring the sampling schedule to the expected signal.^{13–15} The optimal schedule depends on whether the signal is an exponentially damped sinusoid, is cosine modulated, or is stationary (such as that in a constant time experiment).

Figure 5 shows the methyl region of the two-dimensional ^1H – ^{13}C HMQC spectra for a 10 mM sample of the 16-residue peptide $\alpha_1\text{B}$ in D_2O at pH 5.0 and 25°C , obtained with natural abundance of ^{13}C at 9.4 T. The data used to compute the spectra in (a) and (b) consisted of 1024 complex points in the ^1H dimension (t_2) and 128 complex points in the ^{13}C dimension (t_1). The spectrum in Figure 5(a) was computed by windowing with a 30° -shifted sine-bell, and zero filling to 2048 complex points prior to Fourier transformation in t_2 , followed by linear prediction using a filter order of 10 to extrapolate the data to 512 points in t_1 , windowing using a 45° -shifted sine-bell, zero filling to 1024 points and Fourier transformation. The data used to compute the spectrum in Figure 5(b) were obtained similarly to the data for (a) in t_2 , but exponential sampling using an effective decay time of 30 ms was used to collect 128 complex points, selected from a linear schedule of 512 points. Processing in t_2 was performed as before, but MaxEnt reconstruction was performed in t_1 , with values of 10 for def and 0.0554 for λ , and deconvolving a 20 Hz linewidth kernel. The data for Figure 5(c) consisted of 64 points exponentially sampled from a linear schedule of 256 points; the spectrum was computed as in (b). Comparison of (a) and (b) shows that nonlinear sampling in conjunction with MaxEnt reconstruction yields higher resolution than is achieved using conventional data acquisition and processing. In particular, the couplings between the leucine methyl protons and the γ proton are more clearly evident in (b). Comparison of (a) and (c) shows that exponential sampling can also be used to obtain resolution comparable to or better than conventional methods using less data. For long multidimensional experiments, even a reduction by a factor of 2 in experiment time can be significant.

Figure 5 Methyl region of the ^1H – ^{13}C HMQC spectra of $\alpha_1\text{B}$: (a) computed from 128-point (in t_1) conventionally acquired data using linear prediction, extrapolation, windowing, and Fourier transformation, (b) using MaxEnt reconstruction of 128-point exponentially sampled t_1 data, and (c) using MaxEnt reconstruction of 64-point exponentially sampled t_1 data

7.3 Deconvolution

MaxEnt reconstruction can also be used to deconvolve an arbitrary modulation. One application is to deconvolve J modulation. Figure 6 shows the same region of the HMQC spectrum of $\alpha_1\text{B}$ as Figure 5, but MaxEnt reconstruction has been used in the ^1H dimension to deconvolve the 7 Hz coupling. This method is equally applicable to spectra exhibiting antiphase modulation; however, it is only capable of deconvolving a single, fixed modulation frequency.

8 QUANTIFICATION

The nonlinearity of MaxEnt reconstruction is an inherent characteristic, and is responsible for the method's ability to achieve noise suppression without sacrificing resolution to the extent associated with linear filtering (such as the windowed DFT). This nonlinearity has important implications in situations where quantification of peak intensities or volumes is required, such as nuclear Overhauser effect measurements or difference spectroscopy. For difference spectroscopy, it may be sufficient to compute the difference using the time domain data and compute the MaxEnt reconstruction of the difference. This assures that the same

Figure 6 Methyl region of the ^1H - ^{13}C HMQC spectrum of $\alpha_1\text{B}$, with 7 Hz J modulation deconvolved in the ^1H dimension using MaxEnt reconstruction

nonlinearity applies to both experiments. When measuring nuclear Overhauser effects, or otherwise quantifying peak intensities, there are two possible approaches. One is to constrain tightly the reconstruction to match the data, which forces the reconstruction to be more nearly linear (although at the expense of noise suppression). Another is to inject synthetic signals of known relative intensity into the time domain data prior to reconstruction. A calibration curve can then be constructed by quantifying the intensities of the known signals.

The nonlinear nature of MaxEnt reconstruction also renders the S/N a poor estimate of sensitivity. Sensitivity estimates are perhaps best obtained by adding signals of known intensity to the data prior to reconstruction.

9 COMPUTATIONAL COST

The computational cost of MaxEnt reconstruction for one-dimensional spectra is typically 2 orders of magnitude greater than the cost of computing an FFT. For large, multidimensional reconstructions, the elapsed time is dominated by memory requirements, rather than the number of computations: the algorithm described above requires of the order of 16 times the size of the reconstructed spectrum for intermediate storage. While row-wise reconstruction can be used to ameliorate this requirement, fully multidimensional MaxEnt reconstructions remain the province of supercomputer-class machines with large amounts of high-speed random-access memory.

10 CONCLUDING REMARKS

Maximum entropy reconstruction is a powerful method for computing spectral estimates from time domain NMR data that avoids some of the limitations inherent in the discrete Fourier transform. It is more general than parametric methods, such as those based on linear prediction, that are restricted to Lorentzian signals, yet is capable of incorporating prior knowledge about the signal when it is available. The computational cost, while significantly greater than the FFT, is in a range that is practical on modern workstations, even for large data sets. Some of the power of the method stems from its nonlinearity, which dictates that the method must be used cautiously. Its ability to use nonlinearly sampled data

provides a powerful tool for improving the resolution and sensitivity of multidimensional experiments. Used prudently, MaxEnt reconstruction can extend the limits of sensitivity and resolution in NMR, simplify analysis, and enable the study of larger molecules and molecules at lower concentrations than is feasible using the DFT.

1 INTRODUCTION

Nuclear magnetic resonance or NMR has become the cornerstone of modern chemical structure elucidation. The technique is unparalleled in its ability to determine chemical structures by tracking atom-to-atom connectivity. Experiments are now available that allow one to determine homonuclear (^1H – ^1H and ^{13}C – ^{13}C) and heteronuclear (^1H – X where $\text{X} = ^{13}\text{C}$, ^{15}N , ^{19}F and ^{31}P among other heteronuclear pairs) connectivity information that is invaluable in assembling unknown chemical structures. Despite the considerable power of NMR methods, the technique unfortunately suffers from inherently low sensitivity when compared to other analytical spectroscopic methods such as mass spectrometry. This rather stringent limitation has prompted very considerable effort in the development of small volume, high sensitivity NMR probe designs. In part, these efforts have been necessary as it is not always possible to isolate additional sample for analysis.

The earliest detailed description of NMR spectroscopy using small rf coils that the author is aware of is found in the work of Odelblad in 1966.¹ In this study, solenoidal microcoils were used in conjunction with continuous wave (CW) NMR methods to study human cervical mucous secretions. The study examined ^1H chemical shifts and spin-lattice (T_1) relaxation behavior of the secretions. From that study, there was a gap of more than a decade before the pioneering work of Shoolery in 1979.² Shoolery's work focused on the use of 1.7 mm capillary NMR probes for direct observe ^{13}C NMR measurements. Shoolery demonstrated that it was possible to substantially reduce data acquisition times, acquiring decoupled ^{13}C NMR spectra for samples as small as 1 mg of cholesterol in 16 h. Corresponding gains were reported for ^1H spectra, with data acquired for a 1 μg sample of cortisone acetate.

These early studies set the stage for the development of 3 mm micro NMR probes that started in 1991 in a collaboration

between the author, colleagues and staff at Nalorac Corporation. The first report utilizing 3 mm micro NMR probe technology appeared in 1992.³ Using the simple indoloquinoline alkaloid cryptolepine (**1**) as a model compound for the study, the authors reported the acquisition of inverse-detected direct heteronuclear shift correlation HMQC data⁴ using a 12 μg (0.05 μMole) sample of the alkaloid dissolved in 145 μl of d_6 -DMSO in 16 h. These data are shown in Figure 1. Long-range heteronuclear correlations were measured using the substantially less sensitive HMBC experiment⁵ on a 35 μg sample (0.15 μmole) of the alkaloid in 145 μl of d_6 -DMSO in 21 h. These studies ushered in new capabilities for the characterization of small samples by NMR spectroscopy. It would have been necessary to isolate substantially larger samples than those reported for characterization using conventional 5 mm NMR probeheads.

Later in 1992, a direct comparison of the performance of 3 mm and 5 mm inverse-detection NMR probes for the acquisition of heteronuclear shift correlation data was reported.⁶ Using 1 μMole samples of the alkaloid harmaline (**2**) prepared in appropriate volumes for the two probe formats, HMQC spectra were acquired with identical s/n (signal-to-noise) ratios. It took four times as long to acquire comparable s/n data in a 5 mm probe with an identical quantity of sample as for the same data in a 3 mm micro inverse NMR probe design (Figure 2). Clearly, for structural characterization problems when limited quantities of sample are available, there is a significant time advantage to acquiring the data using a 3 mm rather than 5 mm probehead.

Several years after the introduction of the 3 mm micro NMR probes, another innovation appeared in the form of the Varian Nano-probe™.^{7–9} Shoolery, the driving force behind this probe technology, had the vision of having 100% of the sample within the confines of the rf coils of the probe. Obviously, however, this would result in considerable inhomogeneity over the sample due to the discontinuity of the magnetic susceptibility at the cell boundary. To circumvent this problem, the sample cell was oriented at the magic angle, 54.7° , and spun at high speed ($>1\text{ kHz}$) to average all of the magnetic dipoles to zero. The small volume of the nano-cell, 40 μl , makes it well suited to small samples. Nano-probe technology has made it possible to acquire ^1H spectra on samples of an aromatic alkaloid, **1**, as small as 75 ng (32 picomoles)

Figure 1 HMQC spectrum of a 12 μg (0.05 μmole) sample of the alkaloid cryptolepine (**1**) acquired overnight using a 3 mm micro inverse-detection NMR probe. The projection of the 2D data matrix through the proton frequency domain (F_2) is shown immediately above the contour plot; the ^1H reference spectrum is shown at the top

and COSY spectra overnight on an 85 picomole (200 ng) sample of the same model alkaloid.¹⁰ The ^1H spectrum of an 32 picomole sample of cryptolepine (**1**) is shown in Figure 3; the corresponding COSY spectrum is shown in Figure 4. Using a heteronuclear version of the probe in conjunction with specialized processing software, Shoolery demonstrated that an INADEQUATE spectrum of a 3.8 mg sample of sucrose could be acquired in 62 h.⁸ Since the initial development of the Nano-probe, a gradient inverse-detection version of the probe has also been developed yielding impressive results.¹¹ Applications of the Nano-probe for the characterization of small samples are discussed below.

The next step in the development of high-sensitivity, small volume NMR probes was the initial report of the μ -coil NMR probe by Sweedler and co-workers in 1995, which essentially overlapped the development of the nano-probe.¹² Unlike conventional NMR probes or the nano-probe described above, the μ -coil probe was instead a flow probe design, with the rf coil wrapped around a polyimide-coated fused-silica capillary. To obtain usable lineshape, it was necessary to immerse the coil in Fluorinert FC-43 when in use. While a linewidth of 0.6 Hz was initially reported, lineshape, based on visual inspection of figures in the initial report, was evidently not well optimized. Nevertheless, the authors reported a detection limit, defined as a $s/n = 3:1$, for a 19 ng sample of sucrose (56 picomoles) using a 1 min acquisition. It is also worth noting that since the μ -coil probe was a flow probe design that a smaller percentage of the actual sample, <20%, was calculated to be contained within the rf coil of the probe.

Figure 2 Comparison HMQC spectra of 1 μmole samples of the simple alkaloid harmane (**2**). The spectrum shown in the bottom panel was acquired with a sample dissolved in 600 μl of d_6 -DMSO using a 5 mm inverse detection probe. The data were acquired in 23 min. The same quantity of material was dissolved in 160 μl of d_6 -DMSO and the data were acquired using a 3 mm micro inverse probe in 12 min to afford the spectrum shown in the top panel. To achieve comparable signal-to-noise using the 5 mm probe required ~ 70 of data acquisition

Figure 3 Proton NMR spectrum of a 75 ng (32 picomoles) sample of the indoloquinoline alkaloid cryptolepine (**1**, inset structure) acquired overnight using a Varian Nano-probe™. Both the residual water and the protio DMSO signals were suppressed in the experiment. Note the intensity of the ^{13}C satellite lines of the solvent relative to the intensity of the N-methyl group (~ 5.05 ppm) of cryptolepine

In contrast, conventional NMR probe designs can load up to $\sim 80\%$ of the sample within the confines of the rf coils in conventional NMR tubes and $>95\%$ of the sample when Shigemitsu micro cells are employed, or 100% with a nano-cell.

Following the initial report, refinements of the μ -coil NMR probe design have been reported. Designs have included probes for ^{13}C detection, although only labeled samples have thus far been studied.¹³ Multiple solenoidal microcoil probes for possible applications to high-throughput screening have been developed.¹⁴ Susceptibility matching plugs used in conjunction with microcoils have also been described for limited sample applications.¹⁵ Using this approach it was possible to position $\sim 43\%$ of the sample within the coil volume, a substantial improvement over initial flow designs. Perhaps the most interesting report has been a probe design for inverse-detection experiments.¹⁶ In the latter study, the authors reported the acquisition of a ^{13}C decoupled HMQC spectrum of a 13 μg sample of chloroquine diphosphate dissolved in 745 nl of D_2O . These data were acquired by accumulating 32 transients for each of 2048×128 increments of the 2D NMR data matrix. The few applications of the μ -coil probe that have appeared thus far have all been contained in papers reporting the development of these probes and are discussed below.

Following in 1998, the development of 1.7 mm gradient submicro inverse-detection or SMIDG NMR probes was reported.^{17,18} This probe design returned to the 1.7 mm format pioneered in the 1970's by Shoolery.² The SMIDG probe design employs a conventional 1.7 mm NMR tube format that

can be inserted pneumatically as with 5 mm or 3 mm micro NMR probes. Sample volumes range from 22–30 μl depending on the coil dimensions and allow $\sim 78\%$ of the sample to be located within the coil volume when careful sample positioning and shimming are done. In one of the original reports, an 8% cryptolepinone impurity contained in a 0.55 μmole sample of cryptolepine was fully characterized by a combination of GHMQC and GHMBC experiments despite the dynamic range problems inherent to the sample.¹⁸ The SMIDG probe has also been used for a number of low-level, long-range ^1H – ^{15}N 2D NMR studies at natural abundance, dramatically lowering sample requirements for this very insensitive experiment.^{19,20} A number of applications of 1.7 mm SMIDG NMR probe technology for natural product and pharmaceutical impurity characterization have been reported and are discussed below.

In 2001, the development of a 1 mm gradient inverse NMR probe was reported.²¹ Using this probe technology, it was possible to record the HMQC spectrum of a 1 μg sample of ibuprofen (**3**) overnight. To date, there have not been any reported applications of this probe technology to the best of the author's knowledge.

Figure 4 Overnight COSY spectrum obtained using a 200 ng sample of the simple alkaloid cryptolepine (**1**) dissolved in 40 μ l d_6 -DMSO and acquired using a Varian Nano-probe™

More recently, intensive effort has been directed toward the development of cryogenic NMR probes. Thus far, 5 and 3 mm designs have been reported by various manufacturers. Several studies using prototype cryogenic 3 mm probes have been presented as posters^{22–24} and several reports have appeared in the published literature.^{25,26} Cryogenic NMR probes operate by cooling the rf coils to temperatures in the range of 10–25 K to reduce noise; preamplifiers used in conjunction with these probes are also frequently cooled to temperatures in the range of from 40–60 K. Considerable sensitivity gains are obtained by using this complex and technologically demanding design strategy. Early versions of the 3 mm cryogenic NMR probe tested in the author's laboratory gave *s/n* ratios for the anomeric proton of a 2 mM sucrose sample in the range of $\sim$ 180:1. More recent designs have given *s/n* ratios as high as 242:1. In comparison, a conventional 3 mm probe can be expected to give *s/n* ratios in the range of 62–67:1 for the same sample tube. The extremely high sensitivity of the cryogenic NMR probes translates to very considerable time savings to achieve identical *s/n* ratios when compared to conventional NMR probeheads. In the initial report from the author's laboratory using a prototype Nalorac 3 mm CryoSPEC™ (CryoM{H}C500-3) probe²⁵ a 40 μ g sample of strychnine (**4**) was employed as a model compound and HSQC data were acquired. All of the responses were observable in 45 min albeit with noise still present in the spectrum; an essentially noise-free spectrum was recorded in 90 min.

In comparison, to achieve a comparable *s/n* ratio using a conventional 3 mm micro NMR probe, the sample had to be run for 17.5 h, which is a factor of 12.5 in time. These comparative spectra are shown in Figure 5. Although not performed in a small volume probe, still more impressive results have been obtained for long-range ^1H – ^{15}N experiments run on a 2 mg sample of the antibiotic eperezolid (**5**) in 160 μ l of solvent in a 3 mm NMR tube run coaxially in

Figure 5 Comparison of 3 mm gradient inverse triple resonance and 3 mm cryoprobe performance comparison using a 40 μg (120 nanomole) sample of strychnine (**4**). The same sample, prepared by serial dilution, was used for the acquisition of the HSQC spectra (non-gradient) shown in all three panels. The data shown in (a) were acquired by accumulating 32 transients/ t_1 increment as 2048×48 (hypercomplex files $\times 2$) data points, which were linear predicted to 192 points in the second frequency domain and zero-filled to 256 points during Fourier transformation using a Nalorac CryoSPEC 3 mm cryogenic micro inverse NMR probe. The data acquisition time was 90 min. Data shown in (b) were acquired identically except that a conventional Nalorac MIDTG-500-3 gradient inverse 3 mm triple resonance NMR probe was employed. Processing and scaling were identical to the data presented in (a), obviously lower in quality since these data were acquired using a conventional NMR probe. Data shown in (c) were again acquired using the Nalorac MIDTG-500-3 gradient inverse triple resonance probe except that 352 transients were accumulated/ t_1 increment giving an acquisition time of 17.5 h. Processing and scaling were identical to that used to prepare panel (a). S/n ratios in panels (a) (90 min) and (c) (17.5 h) are comparable

Figure 6 Comparison ^1H – ^{15}N CIGAR-HMBC²⁷ 5–10 Hz optimized long-range heteronuclear shift correlation data for the oxazolidinone antibiotic eperezolid (**5**) at natural abundance ^{15}N . The data shown in (a) were acquired using a Varian Cryo-Q 500 MHz HN gradient cryogenic NMR probe in 26 min with a s/n ratio of 101 : 1. To acquire comparable s/n data using a conventional Nalorac MIDTG-500-3 gradient inverse triple resonance probe using the same sample required 17 h 40 min (b)

a 5 mm Varian Cryo-Q 500 MHz HN probe.²⁶ A CIGAR-HMBC²⁷ spectrum in which all of the anticipated long-range ^1H – ^{15}N 2D NMR responses were observed was recorded in 26 min. To achieve comparable s/n ratio in a conventional 3 mm gradient inverse triple resonance probe required 17 h 40 min, corresponding to a factor of 38 in time. These results are shown in Figure 6.

2 HIGH SENSITIVITY, SMALL VOLUME PROBE PERFORMANCE COMPARISONS

One question that immediately comes to the mind of an investigator when faced with the problem of acquiring NMR data for a small sample is what probe should be used? This question has prompted a number of comparisons of various probe formats since the introduction of the 3 mm micro NMR probes in 1992. A complete set of all possible comparisons

is unfortunately not available. Indeed, there are no direct comparisons at all between any of the formats discussed in the contribution vs. any of the μ -coil NMR probes. Nevertheless, those comparisons that have been reported are summarized below.

2.1 3 mm Micro Inverse vs. 5 mm Inverse NMR Probe Performance Comparison

The first comparison of a small volume NMR probe to the standard 5 mm probe was reported in late 1992 following the introduction of the 3 mm micro NMR probes.⁶ Using a 1 μ mole sample of the simple alkaloid harmane (**2**) dissolved in appropriate volumes of d_6 -DMSO for 3 and 5 mm NMR probes, comparison HMQC spectra were recorded. When data were acquired for identical times, the pair of spectra shown in Figure 2 were obtained. The advantage of the 3 mm micro probe over the conventional 5 mm probe when dealing with the 167 μ g (1 μ mole) sample of harmane (**2**) is obvious. When data were acquired in 12 min (4 transients/ t_1 increment, $2048 \times (2 \times 32)$ hypercomplex files) using the 3 mm micro inverse probe, it was necessary to acquire data for 69 min (32 transients/ t_1 increment $2048 \times (2 \times 32)$ hypercomplex files) to achieve comparable performance with a conventional 5 mm inverse-detection probe. These data heralded the beginning of renewed interest in the utilization of high-sensitivity, small volume NMR probes.

2.2 3 mm Micro Dual vs. Heteronuclear Nano-probe Performance Comparison

A rigorous comparison of these probe formats has not been reported. There are, however, several examples in the literature where both probe formats were used to acquire ^{13}C reference spectra. One example is contained in a paper describing the elucidation of the structure of the alkaloid cryptolepicarbolone (**6**) from the Ghanaian plant *Cryptolepus sanguinolenta*.²⁸ The total available sample of the alkaloid was $\sim 100 \mu\text{g}$ ($\sim 0.25 \mu\text{mole}$). The acquisition of a ^{13}C reference spectrum of the alkaloid sample in 40 μl of d_6 -DMSO using a heteronuclear nano-probe was accomplished overnight giving a spectrum with a s/n ratio of 9 : 1. In comparison, the same sample of alkaloid, after transfer to a 3 mm micro NMR probe in the process of which the sample was diluted to 140 μl gave a spectrum with 9 : 1 s/n over a weekend. A similar non-rigorous comparison of the performance of the 3 mm micro dual and heteronuclear nano-probes is found in a report of the characterization of an N-acetyl keto derivative of fumonisins-B₁ (**7**).²⁹ An overnight acquisition of a ^{13}C reference spectrum of an $\sim 200 \mu\text{g}$ sample of the material gave a carbon spectrum with a s/n ratio of 5.5 : 1 when a 3 mm micro dual probe was employed. Curiously, a ketone carbonyl resonance expected on the basis of mass spectrometric fragmentation data was not observed in the spectrum. The acquisition of the ^{13}C reference spectrum was repeated with the same sample after concentration to 40 μl to allow the use of a heteronuclear nano-probe. The overnight nano-probe acquisition gave a spectrum with a s/n ratio of 11 : 1 and the carbonyl resonance at 219.5 ppm was observed in the spectrum. These data are presented in Figure 7. There is no obvious reason why carbonyl resonance wasn't observed in the spectrum recorded using the 3 mm micro dual probe;

Figure 7 Overnight ^{13}C reference spectra of an $\sim 200\text{ }\mu\text{g}$ sample of a secondary fungal metabolite, fumonisins- B_1 (7), in D_2O . The data shown in the top panel were acquired using a 3 mm micro dual NMR probe in $145\text{ }\mu\text{l}$ of solvent and gave a signal-to-noise ratio of 5.5:1. A ketone carbonyl resonance expected on the basis of mass spectrometric fragmentation data was not observed in the spectrum. Following the concentration of the sample to $40\text{ }\mu\text{l}$ to allow the use of a heteronuclear Nano-probeTM, the data shown in the bottom panel were acquired. The overnight Nano-probeTM acquisition gave a spectrum with a s/n ratio of 11:1 and the carbonyl resonance at 219.5 ppm was observed in the spectrum

the relaxation delay between transients was identical. From these data, however, it can be concluded that the per transient efficiency of the conventional micro dual probe is somewhat better than that of the nano-probe. This conclusion derives from the nearly four-fold concentration of the sample for acquisition of the nano-probe data. If probe efficiencies were identical, a s/n ratio for the nano-probe approaching 22:1 should have been obtained on the basis of the concentration factors.

2.3 1.7 mm SMIDG vs. 3 mm Micro Inverse Probe Performance Comparison

A rigorous comparison of the 1.7 mm submicro gradient inverse or SMIDG and a 3 mm micro inverse detection NMR probes has been reported for both ^1H – ^{13}C direct and long-range and ^1H – ^{15}N long-range heteronuclear shift correlation experiments.³⁰ In addition, the results obtainable by running a 1.7 mm sample coaxially in a 3 mm micro probe were also reported in this study. Using an $0.5\text{ }\mu\text{mole}$ sample of the non-steroidal anti-inflammatory agent ibuprofen (3) in either 30 or $150\text{ }\mu\text{l}$ of d_6 -DMSO, gradient ^1H – ^{13}C HSQC spectra were acquired using both probes. Data accumulation for the three experiments performed was 48 min for each spectrum. Using the 1.7 mm SMIDG probe, a s/n ratio of 148:1 was obtained. All of the expected responses were observed in the spectrum, including that of the relatively weak *sec*-butyl methine resonance. When the 1.7 mm sample was run in the 3 mm micro inverse probe, again all of the responses were observed; the s/n ratio was 75:1. When the GHSQC data were acquired using the 3 mm micro inverse probe, the *sec*-butyl methine resonance was absent from the spectrum; the s/n ratio was 62:1. Similar results were obtained for the same series of ^1H – ^{13}C GHSQC experiments using a $1\text{ }\mu\text{mole}$ sample of strychnine (4). These comparison GHSQC spectra are presented and described in Figure 8.

Using a 1 mg sample of strychnine (4), long-range ^1H – ^{15}N GHMBC experiments were also performed using both the 1.7 mm SMIDG and the 3 mm micro inverse probes; these data are presented in Figure 9. The 1.7 mm SMIDG data gave all of the expected long-range ^1H – ^{15}N responses;^{30–33} all responses were well above the noise floor of the spectrum. When the 1 mg sample in the 1.7 mm tube was run coaxially in the 3 mm micro inverse probe, again, all of the expected long-range responses to the two strychnine nitrogen resonances were observed although there were some noise spikes contained in the spectrum with comparable intensity to the desired, long-range responses. For the 3 mm sample, all but one of the expected long-range responses was observed. However, there were substantial numbers of spurious peaks with greater intensity than the desired long-range responses. It was concluded that a sample containing $\sim 3\text{ }\mu\text{moles}$ ($\sim 1\text{ mg}$ in the case of strychnine) was borderline for an overnight long-range ^1H – ^{15}N 2D NMR experiment at natural abundance in a 3 mm probe.

2.4 Conventional vs. Cryogenic NMR Probe Performance Comparison

To date there are two studies in the literature that report comparisons of conventional and cryogenic NMR probe performance. The first is a direct comparison of 3 mm cryogenic inverse and conventional 3 mm inverse-detection probes.²⁵ Using a $40\text{ }\mu\text{g}$ (120 nanomoles) sample of strychnine dissolved in $150\text{ }\mu\text{l}$ d_6 -benzene, identical HSQC spectra were recorded using a Nalorac 3 mm CryoSPEC inverse probe and a conventional Nalorac Z•SPECTM MIDTG-500-3 gradient inverse-detection probe. With the cryogenic probe, all of the aliphatic direct correlation responses were observable within 45 min and a noise-free spectrum was obtained in 90 min. To achieve a comparable s/n ratio using the conventional probe required 17 h of data acquisition. With the initial prototype

Figure 8 Comparison 600 MHz ^1H – ^{13}C GHSQC spectra acquired for a $1\ \mu\text{mol}$ sample of strychnine (**4**) in CDCl_3 in either a 1.7 or 3 mm NMR tube in a volume appropriate to the tube format. All data were acquired by accumulating four transients at each of 64 increments of the evolution time, t_1 , giving identical data acquisition times. All data were processed and scaled identically to prepare the three panels shown. Data shown in (a) were acquired using a 1.7 mm sample in a Nalorac SMIDG-600-1.7 submicro gradient inverse detection NMR probe; using the region from 5.5 to 4.5 ppm as representative noise, the s/n ratio for this spectrum was 112:1. The data shown in (b) were acquired by running the 1.7 mm sample coaxially in a conventional Nalorac MIDTG-600-3 gradient triple resonance micro inverse NMR probe. The s/n ratio for these data was 75:1. Finally, the data shown in (c) were acquired using a $1\ \mu\text{mol}$ sample in a 3 mm tube, the data again acquired using the conventional Nalorac MIDTG-600-3 probe. The s/n ratio for this experiment was 62:1. Projections through the F_2 frequency domain are plotted above each of the contour plots to provide a more effective portrayal of the relative s/n ratio in the three experiments

cryoprobe used for this comparison, a $3.5\times$ improvement in signal-to-noise was afforded by the cryoprobe, which corresponds to a 12.5-fold time advantage to equivalent signal-to-noise. The comparison 90 min HSQC spectra are shown in Figure 5.

More recently, a comparison was drawn for the acquisition of long-range ^1H – ^{15}N 2D experiments at natural abundance.²⁶ Using a 2 mg sample of the oxazolidinone antibiotic eperezolid (**5**) dissolved in $160\ \mu\text{l}$ d_3 -acetonitrile in a 3 mm NMR, ^1H – ^{15}N CIGAR-HMBC 2D NMR spectra optimized for a long-range coupling range of from 5 to 10 Hz^{34–36} were acquired using a Varian 5 mm Cryo-Q HN probe (because of the considerable variability of long-range ^1H – ^{15}N couplings, it is advisable to use an accordion-optimized long-range 2D NMR experiment such as IMPEACH-MBC or CIGAR-HMBC to record long-range ^1H – ^{15}N 2D NMR spectra at natural abundance. See Ref.³⁴). In less than 10 min, most of the anticipated long-range ^1H – ^{15}N responses were observed. A second experiment run in 26 min afforded a spectrum with 101:1 (projecting through the F_1 or ^{15}N frequency domain) s/n in which even the weakest response had $\sim 40:1$ s/n. Acquisition of a 26 min data set using a conventional Nalorac Z•SPEC MIDTG-500-3 gradient inverse probe gave only the N7-9CH₃ response. A longer 4 h experiment gave all of the expected long-range responses albeit with $<50:1$ s/n.

To attain a s/n ratio comparable to that of the 26 min cryoprobe experiment, it was necessary to acquire data with the conventional 3 mm probe for 17 h 40 min (112:1 s/n). A comparison of the 26 min 5 mm cryoprobe data with the 17 h 40 min 3 mm ^1H – ^{15}N CIGAR-HMBC spectra optimized over the range of 5–10 Hz is shown in Figure 6. Thus, for long-range ^1H – ^{15}N experiments, the cryogenic NMR probe afforded a $>38\times$ time advantage relative to a conventional 3 mm micro probe despite potential losses of signal due to filling factor associated with running a 3 mm tube coaxially in the 5 mm probe. Unfortunately, at present, it is not possible to make a direct comparison of 3 mm NMR probes for long-range ^1H – ^{15}N 2D NMR experiments at natural abundance as a 3 mm cryogenic NMR probe with an X-coil tunable to ^{15}N or doubly tuned to ^{13}C and ^{15}N has yet to be developed.

While 5 mm cryogenic NMR probes are not in the category of small volume NMR probes by any means, the extremely high sensitivity which they offer makes them competitive when dealing with small samples, particularly when 3 mm tubes are run coaxially or specialized micro cells are employed to restrict sample volume. To date, there have not been any reports of tubes smaller than 3 mm in diameter being run coaxially in a cryogenic probe; it is likely that filling factor losses would substantially offset the gains in sensitivity offered by the probe if a small tube such as 1.7 mm were run coaxially in a 5 mm cryogenic probe. Thus, it is likely that as cryogenic probes

Figure 9 Comparison ^1H – ^{15}N 8 Hz optimized GHMBC spectra of 3 μmole samples of strychnine (**4**) at natural abundance prepared in either a 1.7 or 3 mm NMR tube in a volume appropriate to the tube format. All spectra were recorded at 600 MHz, accumulating 4096 transients for each of 40 increments of the evolution time, t_1 , giving identical 18 h data acquisitions. The data shown in (a) were acquired using a 1.7 mm sample in a Nalorac SMIDG-600-3 gradient inverse submicro NMR probe. Again using the region of the proton spectrum from 5.5 to 4.5 ppm for representative noise, the SMIDG data gave a s/n ratio of 60 : 1. All anticipated responses were observed either directly in the contour plot or readily in the traces from the N9 amide or N19 aliphatic nitrogen resonances. When the 1.7 mm sample was run coaxially in a Nalorac MIDTG-600-3 gradient inverse triple resonance probe, the data shown in (b) were obtained, giving a s/n ratio of 41 : 1. Some spurious responses are observed in the projection through F_2 as well as in the contour plot. Finally, when a 3 mm sample was used in a 3 mm probe, the result shown in (c) was obtained. In this case, spurious responses in the projection are of greater intensity than some legitimate responses, suggesting that either a longer data acquisition or larger sample would be desirable with this probe technology to obtain reliable data. The s/n ratio of the spectrum shown in (c) was 26 : 1

become more widely available that 5 mm versions of this probe technology will be used to deal with small NMR samples in those labs not equipped with more specialized probeheads.

2.5 Conventional NMR Tubes vs. Specialized Sample Cells

One alternative available to researchers without access to any of the specialized NMR probeheads described in this contribution is to use a specialized sample cell to restrict overall sample volume, thereby keeping a greater percentage of a scarce sample within the confines of the rf coils of the probe being used. Various tactics have been employed to achieve this goal. Approaches have included the development of plastic NMR tube inserts, the properties of which are matched as closely as possible to those of the solvent being employed. Shigemitsu, using a more novel approach, has employed specialized glass that matches the magnetic susceptibility of several NMR solvents, to make both the NMR tube and a precision bore ‘plunger’. Tubes have been manufactured thus far for use with CDCl_3 , CD_3OD , D_2O and d_6 -DMSO. With a conventional 5 mm NMR tube, sample volumes can be reduced from $\sim 500 \mu\text{l}$ to roughly 225–250 μl . The resulting two-fold increase in sample concentration will correspondingly quarter acquisition time to a given s/n ratio.

To date, two studies have appeared in the literature that compare the results obtainable with normal NMR tubes vs. specialized NMR cells. The earliest report was a study of Caribbean ciguatoxin.³⁷ A substantial improvement in the HMQC data that could be recorded for an $\sim 0.95 \mu\text{mole}$ sample of Caribbean ciguatoxin was noted when the data were acquired in 67 μl d_5 -pyridine when the sample was run in a 3 mm Shigemitsu D_2O -matched micro NMR cell (despite the mismatch of the solvent to the optimization of the micro cell) vs. data acquired in 120 μl in a conventional 3 mm NMR tube. No quantitative comparison was drawn. A similar improvement was noted by Reynolds, Yu and Enriquez³⁸ for ^{13}C -detected 2D heteronuclear NMR experiments when run in Shigemitsu micro NMR cells vs. data acquired in normal 3 mm NMR tubes. Although 1.7 mm Shigemitsu cells have been developed, there have not been any reported applications of this type of tube in the literature.

3 APPLICATIONS OF SMALL VOLUME NMR PROBES IN THE SOLUTION OF CHEMICAL STRUCTURE PROBLEMS

There is a wide range of potential applicability of specialized NMR probe technology in the solution of structural

problems, not all of which have yet been reported. Some research areas where specialized NMR probe heads can be highly advantageous include: characterization of scarce natural product samples; identification of metabolites of pharmaceuticals; characterization of forensic samples; protein characterization; and the identification of chemically unstable species. Given that the first of the new generation of small volume specialized probes to be described were the 3 mm micro inverse and dual probes, applications utilizing these probeheads will be surveyed first, followed by applications utilizing Nano-probe technology. To date, there have not been any applications of μ -coil probes in the solution of structural problems of which the author is aware. The examples that have been reported in conjunction with the development of this probe technology will be summarized next. Examples of potential applications and structural problems solved using 1.7 mm SMIDG probes, and then cryogenic probe applications will complete this section.

3.1 Existing Reviews

Several reviews have been published that deal with either probe-specific or the general topic of small sample NMR spectroscopy.^{39–44} Various aspects of dealing with small samples by NMR have also been discussed in reviews of specific classes of molecules, which include alkaloids,⁴⁵ carbohydrates,⁴⁶ and a recent review of long-range ^1H – ^{15}N 2D NMR applications.⁴⁷

3.2 Applications of 3 mm Micro Probes

Following the initial reports on the development of 3 mm micro NMR probe technology in the authors laboratories, then at Burroughs Wellcome, Co., the first reported 'real world' application of this technology was in the characterization of a 30 μg (0.07 μmoles) metabolite sample through the use of a combination of 3 mm micro and heteronuclear nano-nmr probe technology.⁴⁸ A heteronuclear nano-nmr probe was used to record a ^{13}C reference spectrum and a homonuclear nano-nmr probe was used to record a COSY spectrum. Following transfer of the sample and dilution to 120 μl , heteronuclear shift correlation spectra were recorded using a 3 mm micro inverse NMR probe. In 1995, the structure of an N-acetyl keto derivative of fumonisins-B₁ (**7**) was determined, again using a combination of probeheads. Two-dimensional NMR spectra were recorded using a 3 mm micro probe while a ^{13}C reference spectrum was recorded using both a 3 mm micro dual and heteronuclear nano-nmr probe. Interestingly, the keto resonance at 219 ppm was not observed in the data from the 3 mm micro dual probe while it was readily observed in the data recorded with the nano-nmr probe.²⁸ Later in 1995, the structure of the complex indoloquinoline alkaloid cryptolepicarboline was reported.²⁷ The homo- and heteronuclear 2D NMR data were recorded using a 3 mm micro inverse nmr probe. A comparison of the ^{13}C spectra recorded using a 3 mm micro dual and heteronuclear nano-nmr probe were also contained in the report.²⁷ Later in 1995, in a report by the author and co-workers³⁷ the benefits of using reduced volume Shigemi micro nmr cells was reported in the context of a study of Caribbean ciguatoxin. In a related study, the proton and carbon NMR spectra of the marine toxin brevetoxin-2 were fully assigned on less than 1 μmole of material through the use of 3 mm micro nmr probe technology.⁴⁹

Late in 1995, the structure of the indolobenzazepine alkaloid homocryptolepinone, which serves as a structural component of the complex spiro nonacyclic alkaloid cryptospirolepine, was reported.⁵⁰ Continuing in the indoloquinoline series of alkaloids in 1996, two new members of this series with novel ring fusion between the indole and quinoline portions of the molecule were reported.⁵¹ Cryptosanguinolentine was based on an indolo[3,2-*c*]quinoline ring fusion rather than the more common [3,2-*b*] ring fusion. Cryptotakiine was based on an indolo[2,3-*b*]quinoline ring system which placed both annular nitrogens on the same side of the molecule. Later in 1996 the structure of the novel, dimeric alkaloid cryptomisine was reported.⁵²

In 1997, Reynolds and co-workers,³⁸ as noted above, examined the limits of ^{13}C detected heteronuclear shift correlation experiments through the combined usage of 3 mm micro probes and Shigemi micro nmr cells. Although the sensitivity of ^{13}C -detected heteronuclear 2D nmr methods is inarguably lower than that of newer, proton-detected methods, there are still occasions when high digitization requirements in the ^{13}C frequency domain are better addressed by direct ^{13}C detection, provided that sufficient sample is available.⁵³

3.3 Applications of Nano-nmr Probes

Magic angle spinning (MAS) liquid NMR probes, or nano-nmr probes as they are frequently referred to *in lieu* of Varian's trademarked Nano-probe™ nomenclature, have been applied in the study of a diverse range of chemical structure problems. A very useful subdivision of these applications is suggested in the review by Keifer.³⁹ For discussion, it is convenient to separate applications into heterogeneous and homogeneous sample types. The former encompasses samples as diverse as whole cells, tissue samples and solid phase synthesis (SPS) supports used for combinatorial chemistry and related applications. Homogeneous samples, as the name implies, refers to solutions in the usual NMR sense.

3.3.1 Heterogeneous Samples

Nano-nmr probes, which spin at the magic angle (54.7°) at speeds of up to several KHz, are quite useful for the study of heterogeneous samples. The earliest such application, of which the author is aware, is a 1994 report dealing with SPS beads on which the synthetic chemistry was being carried out. The first report, which employed ^1H NMR, used a Varian homonuclear Nano-probe.⁵⁴ Results that can be obtained with various SPS resins using various types of probes were reported in 1996 by Keifer and co-workers.⁵⁵ The effect of tether length between the resin and the synthetic site has been examined⁵⁶ as has the use of MAS liquids probes to monitor the extent of reaction completion on SPS supports.^{57,58} More recently, Seffler and Gerritz⁵⁹ have used 1D and 2D NMR methods to characterize reaction products bound to Chiron SynPhase crowns used in the elaboration of combinatorial chemical libraries. Finally, although not chemically bound, Mohri and co-workers⁶⁰ have studied the mobility of surface-adsorbed molecules on insoluble pigment particles using ^1H T_1 relaxation measurements in a nano-nmr probe. Reviews on the analysis of materials on solid supports include those of Keifer³⁹ and Gallop and Fitch.⁶¹

Another interesting heterogeneous nano-nmr probe application has been used in an attempt to biochemically classify kidney carcinoma biopsy samples.⁶² While by no means a rapid analytical or screening tool, this study does provide a glimpse of where the probe technology may be applied in the future.

3.3.2 Homogeneous Samples

Numerous reports of applications of nano-nmr probes to homogeneous solution samples have been reported. Broadly, these applications can be further subgrouped into natural products or small molecules and biomacromolecule studies. One of the first reported small molecule applications was a combined 3 mm micro NMR probe/nano-nmr probe study of a metabolite structure.⁴⁸ The 3 mm micro probe was used to record the heteronuclear 2D nmr data on a 30 µg sample of a low molecular weight metabolite while a heteronuclear nano-nmr probe was used to record the ¹³C reference spectrum. Combined 3 mm micro probe/nano-nmr probe applications have also been reported in the elucidation of a complex indoloquinoline alkaloid structure²⁷ and a fumonisins-B₁ fungal metabolite structure.²⁸ In both of these studies, comparative ¹³C NMR spectra acquired in a 3 mm micro dual probe and a heteronuclear nano-nmr probe are presented. Another combined 3 mm micro probe/nano-nmr probe application is found in the structural characterization of laingolide, a novel 15-membered macrolide from a blue green alga.⁶³ In this study, the direct and long-range heteronuclear chemical shift correlation experiments were performed in a 3 mm micro probe while the ¹³C reference spectrum was recorded using a heteronuclear nano-nmr probe.

The sensitivity of heteronuclear nano-nmr probes, combined with the small volume of a nano cell (40 µl) has led to the application of this probe technology for the characterization of a novel steroid skeleton⁶⁴ through the use of the INADEQUATE^{65,66} experiment.

More recently, several additional applications of nano-nmr probe technology have been reported in the characterization of natural product samples. Bierer and co-workers⁶⁷ reported using a nano-nmr probe in the characterization of the indoloquinoline alkaloid cryptolepinone, which was independently characterized by Martin and co-workers⁶⁸ using 3 mm micro probe hardware. A modified tetrapeptide, lyngbyapeptin A, has been characterized, in part, using nano-nmr to acquire a ¹³C reference spectrum.⁶⁹ Lyngbyapeptin A was described as being produced by a cyanobacterium in 'trace' amounts and thus it is likely that the heteronuclear shift correlation data were recorded using a 3 mm micro NMR probe although this was not specified in the report. Most recently, the structure of a new macrocyclic trichothecene produced by a marine-derived fungus has been reported.⁷⁰ In this case, a Varian Nano-probe was used for the acquisition of all of the NMR data reported, including the heteronuclear shift correlation spectra.

The first reported application of nano-nmr probes in the study of biomacromolecules is found in the report of Manzi et al.⁷¹ on the identification of a novel glycosaminoglycan core-like molecule. Delepierre and co-workers⁷² next reported studies of the structure of a potassium channel blocking toxin (peptide) from the scorpion *Pandinua imperator* using a homonuclear nano-nmr probe. That report was followed by another from the same laboratory that examined the kinetics of secondary structure recovery during the refolding of reduced

hen egg white lysozyme.⁷³ Further work on potassium channel blocking peptide toxins was also reported later in 1997 by Delepierre and co-workers.⁷⁴ Delepierre and colleagues⁷⁵ next reported the results of a study of renatured lysozyme using nano-nmr techniques. In 1999, Delepierre, et al.,⁷⁶ reported the analysis of the structure of Pi7, an orphan peptide from the scorpion *Pandinua imperator* using ¹H nano-nmr methods. Van Halbeek and co-workers⁷⁷ initiated studies of glycan classes and their analysis by nano-nmr methods that were first reported in 2000. Finally, the biosynthesis of ganglioside mimics of *Campylobacter jejuni* has been studied at the nanomole level through the use of nano-nmr methods.⁷⁸

Most recently, Kupce et al.⁷⁹ have examined the issue of adiabatic TOCSY MAS in liquids, demonstrating that adiabatic mixing sequences are less susceptible to modulation effects due to both rf and magnetic field homogeneities than are conventional mixing sequences.

3.4 Applications of Small Volume Cryoprobes

To date, only a scant few reports on the use of small volume cryogenic NMR probes have been reported. Withers and co-workers²²⁻²⁴ have presented several posters describing the utilization of a 2.5 or 3 mm cryogenic probes for the acquisition of heteronuclear shift correlation data needed for metabolite characterization. The author and colleagues²⁵ have reported a comparison of conventional and cryogenic 3 mm NMR probes using a 40 µg (120 nanomoles) sample of strychnine (**4**) shown in Figure 5. Finally, although not using a small volume cryogenic probe, the author and co-workers²⁶ have reported a comparison of long-range ¹H-¹⁵N heteronuclear shift correlation data (shown in Figure 6) acquired using a 3 mm sample in both a 5 mm cryogenic and conventional 3 mm NMR probes. Undoubtedly more applications of small volume cryogenic probes will appear given the substantial sensitivity advantage which these probes afford.

3.5 Phase Cycled vs. Gradient NMR Experiments When Dealing with Very Small Samples

Work in the author's laboratories at Pharmacia, directed to the characterization of very small samples of isolated and impurities of potential drug candidates, has shown that at very low concentrations the use of gradient NMR experiments is disadvantageous. Reynolds and Enriquez⁸⁰ after a discussion of this observation have gone on to report a rigorous experimental verification of this observation. They demonstrated that at high concentrations, the t₁ ridges due to incomplete suppression of ¹H-¹³C components of magnetization (or that from protons bound to heteroatoms) constitutes the main source of noise in phase-cycled 2D NMR spectra. Gradient NMR pulse sequences strongly suppress this noise, as would be expected. This observation is consistent with the generally accepted advantage of gradient-based NMR experiments when only a few transients/t₁ increment will be accumulated. However, as also reported by Reynolds and Enriquez, the intensity of the t₁ ridges appears to be directly proportional to the signal strength and consequently, for very dilute samples, t₁ ridges contribute to the total noise in an HMBC experiment to only a minor extent. When sufficient numbers of transients are accumulated

per t_1 increment, the intrinsically higher sensitivity of phase-cycled experiments vs. gradient-based experiments makes the former preferable.

To illustrate this observation rather dramatically, Russell⁸¹ has recorded gradient and phase-cycled HMBC data for a 20 μg sample of retrorsine (**8**). These data are shown in Figure 10 compared to data from a 700 μg sample of the same molecule. The 700 μg data were acquired overnight at 500 MHz using a conventional Nalorac MIDTG-500-3 gradient micro inverse 3 mm NMR probe and provide a references for the responses expected to be observed in the spectrum.

The reference gradient HMBC spectrum acquired overnight using the 700 μg sample of the alkaloid is shown in Figure 10 Panel a and contains all of the responses expected for the molecule. The phase-cycled, non-gradient HMBC spectrum acquired using a 20 μg sample of the alkaloid in 160 h is shown in Panel b. A significant percentage of the possible responses are observed in the spectrum, particularly when traces for the individual carbons are extracted from the data matrix. In contrast, the gradient HMBC spectrum on the same 20 μg sample after an identical data acquisition, shown in Panel c, shows only the most intense responses in the spectrum. This result is consistent with the work of Reynolds and Enriquez⁸⁰ which was done with substantially larger samples.

4 CONCLUSIONS

Small volume, high sensitivity NMR probes have had a significant impact on the conduct of research in many areas of chemistry and biochemistry that depends on NMR methods since the first reports on the contemporary versions of these probes appeared about a decade ago. Probes have been developed in a number of formats for conventional tube configurations including 3, 2.5, 1.7 and 1 mm. New probe technologies such as Varian's Nano-probe and the μ -Coil probes have also been reported. The development of small volume, cryogenic NMR probes is now on-going. With the continuing developments and refinements in this rapidly advancing field of NMR research, sample requirements have concomitantly decreased. COSY spectra on samples as small as 200 ng of cryptolepine (**1**), HMQC spectra on 1 μg of ibuprofen (**3**), and HMBC spectra on 6 μg of cryptolepinone, an oxidative degradation product contained in a sample of cryptolepine (**1**) have been discussed in this report. While it is difficult to foresee how much further sample requirements will diminish in the coming years, it is assured that with the advent of small volume, cryogenic NMR probes that the frequency of studies with very small samples will increase in the near future.

Figure 10 Comparison HMBC spectra of retrorsine (**8**).⁸¹ The 8 Hz optimized gradient HMBC reference spectrum shown in panel (a) was acquired overnight using a 700 μg sample of the alkaloid dissolved in 150 μl of d_4 -methanol. The data shown in panels (b) and (c) were accumulated using a 20 μg sample of the alkaloid dissolved in 150 μl of d_4 -methanol. The data shown in panel (b) were acquired using a conventional phase-cycled, non-gradient HMBC pulse sequence. In comparison, the data shown in panel (c) were obtained using the more contemporary gradient HMBC experiment. The superior performance at these low levels of the phase-cycled non-gradient HMBC experiment is consistent with the recent report of Reynolds and Enriquez⁸⁰

1 INTRODUCTION

Liquid crystals can be loosely defined as materials with properties intermediate between those of solids and liquids (mesophases). Liquid crystals typically flow like viscous liquids but the phase exhibits some degree of molecular packing or structure whereby individual molecules tend to align, making the mesophase anisotropic.

1.1 NMR in Liquid Crystalline Solvents

Most molecules that form a nematic mesophase are able to dissolve a small amount of solute compound without destroying the mesophase. Since the first reports of using liquid crystals as solvents for NMR spectroscopy, high resolution NMR in liquid crystalline solution has developed into an important area.¹ The amount of solute that can be dissolved in a nematic mesophase depends on the mesophase and the solute, but solute concentrations of 5 wt % are common and concentrations of 10–15 wt % are sometimes achievable without disrupting the liquid crystalline properties of the solvent.

The motion of solute molecules dissolved in a nematic mesophase is restricted by the arrangement of the mesophase molecules. The anisotropy of the arrangement of the solvent molecules induces anisotropy in the movement of the solute molecules via dispersion forces. A solute dissolved in an oriented mesophase is forced to undergo nonrandom (anisotropic) motion because of its interactions with the aligned solvent. If the nematic mesophase is aligned in a magnetic field then alignment of the mesophase is reflected in the anisotropy of the motion of the solute molecules.

The rapid motion of molecules in an oriented mesophase results in the averaging of the intermolecular dipolar interactions to zero. However, the intramolecular dipolar interactions have a nonzero average.

Qualitatively the NMR spectra of solutes oriented in mesophases are more complex than the spectra obtained in isotropic solvents, for two reasons (see *Liquid Crystalline Samples: Spectral Analysis*):

1. The nonzero averaging of dipolar couplings results in many more coupling constants (splittings) being expressed in the spectrum. A dipolar coupling constant appears for every pair of interacting nuclei.
2. The magnitude of the dipolar coupling constants (D_{ij}), between a pair of interacting nuclei is generally large (up to a few kilohertz) compared with the indirect coupling constants (typically a few hertz). This results in virtually all spectra of solutes dissolved in an oriented mesophase being highly second order and adds to the spectral complexity.

2 MULTIPLE QUANTUM NMR OF SAMPLES DISSOLVED IN LIQUID CRYSTALLINE SOLVENTS

The signals observed in a conventional NMR spectrum (single rf pulse followed by signal acquisition and FT of the resulting FID) are governed by selection rules which dictate that transitions can only be induced between energy levels differing in total spin quantum number by $\Delta M = \pm 1$ (single quantum transitions). Multiple quantum NMR (MQ NMR)² is concerned with the observation of nuclear transitions where $\Delta M \neq \pm 1$.

The number of transitions in the single quantum NMR spectrum of a solute dissolved in an anisotropic solvent increases rapidly with the number of coupled spins. A molecule with a single proton would have a ^1H spectrum with only one transition. A system containing two protons would have four possible transitions, and a spin system composed of three nonequivalent protons has 15 transitions.

The number of transitions for an unsymmetrical spin system (disregarding symmetry considerations) can be calculated as³

$$\text{No. single quantum transitions} = (2N)! / [(N-1)!(N+1)!] \quad (1)$$

This is an exponential function where the number of transitions increases dramatically as the number of interacting spins increases (Figure 1). In an 8-spin system there would be 1.14×10^3 transitions in the single quantum spectrum; in a 10-spin system there would be 1.67×10^5 transitions.

If there is symmetry present in the spin system (i.e. chemically or magnetically equivalent nuclei) the number of transitions is reduced. For the symmetrical six proton spin system of benzene there are 72 transitions, compared with 792 transitions in a six proton system with no symmetry.

Given a reasonable linewidth for each transition, substantial overlap occurs in the single quantum spectrum of a large spin system, and the spectrum rapidly degenerates to an unresolved broad lump. In higher spin systems, it becomes impossible to resolve or assign individual transitions for an iterative computer analysis. MQ NMR can considerably reduce the complexity of the spectrum of a solute dissolved in a liquid crystalline solvent, and the main benefit of MQ NMR lies in the fact that there are fewer transitions in the very high MQ spectra.

Figure 1 The number of single quantum transitions as a function of the number of interacting nuclei ($I = \frac{1}{2}$)

The number of M quantum transitions in a system of N nuclei ($I = 1/2$), neglecting symmetry, is given by

$$\text{No. of } M \text{ quantum transitions} = (2N)! / [(N - M)!(N + M)!] \quad (2)$$

Representative values are summarized in Table 1.

In the N quantum spectrum of an N -spin system, there will always be only one transition. The $(N - 1)$ quantum spectrum of an N -spin system will contain only $2N$ transitions. For large N , the $N - 1$ and $N - 2$ quantum spectra will contain only a few transitions and will be much less complex and more easily analyzed than the single quantum spectrum.

3 EXCITATION OF MULTIPLE QUANTUM COHERENCES

Coherence between states separated by $\Delta M \neq 1$ cannot be observed directly, but is usually detected indirectly by

its modulation of single quantum coherence in a two-dimensional NMR experiment. A two-dimensional NMR experiment⁴ for exciting and detecting MQ spectra can be divided schematically into five time frames, as shown in Table 2.

Providing that MQ coherences (MQCs) can be produced by a suitable preparation sequence, and mixed to observable single quantum coherence with an appropriate 'mixing' sequence, the MQ frequencies of a spin system can be obtained by systematically varying the duration of the 'evolution' period (t_1) followed by Fourier transformation over t_1 . Compared with samples in isotropic solution, MQCs can be excited relatively easily in samples dissolved in liquid crystalline solution. The large dipolar coupling constants expressed ensure that coherences evolve rapidly and MQC can be excited efficiently before the effects of relaxation complicate coherence development in the spin system.

3.1 Nonselective Excitation

The most common (and simplest) method for preparing MQC is by use of two $\pi/2$ pulses separated by a fixed delay. The simplest mixing sequence is a single $\pi/2$ pulse and this means that a three-pulse sequence (Figure 2) can be used to record multiple quantum spectra.

The sequence of two hard pulses in the preparation part in Figure 2 nonselectively generates coherence of all orders possible in the spin system. Coherences are not excited uniformly and the efficiency with which MQC is excited depends specifically on the couplings and chemical shifts of the nuclei in the spin system and the choice of the interval d_1 . Broad band excitation techniques have been proposed⁵ where the value of d_1 in the preparation sequence is varied either in a pseudorandom or systematic fashion to achieve a more uniform excitation in the multiple quantum domain. Weitekamp et al.⁶ have devised an experimental search procedure for optimizing the delays in the preparation period of the MQ excitation sequence.

Table 1 The Number of Transitions in the M Quantum Spectra as a Function of the Number of Interacting Nuclei ($I = \frac{1}{2}$)

ΔM	Number of spins ($I = \frac{1}{2}$)						
	2	4	6	8	10	15	20
1	4	56	792	11440	1.68×10^5	1.45×10^8	1.31×10^{11}
2	1	28	495	8008	1.26×10^5	1.19×10^8	1.13×10^{11}
4		1	220	1820	38760	5.46×10^7	6.28×10^{10}
6			1	120	4845	1.43×10^7	2.32×10^{10}
8				1	190	2.04×10^6	5.58×10^9

Table 2 The Five Time Frames in the Two-dimensional MQ NMR Experiment^a

Relaxation	Preparation	Evolution	Mixing	Detection
Spin system relaxes between experiments	Generate MQC in the coupled spin system	MQC evolves with time (t_1)	Mixes MQC to observable SQC	Detect SQC as a FID (t_2)

^aMQC, multiple quantum coherence; SQC, single quantum coherence.

Figure 2 Three-pulse sequence for the observation of MQ spectra

3.2 Selective Excitation

Nonselective excitation of MQC excites all possible coherences, but leaves most of the spectral intensity in the single quantum and low multiple quantum spectra because these spectra have the most transitions.^{3b} As a result, the simpler high-order coherences are comparatively weak. An alternative approach to the excitation of MQC is selectively to excite only a few orders of coherence and more effectively channel or focus the available signal into one order (or a few selected orders).

Order selective excitation has been achieved by the use of phase-cycled sequences of rf pulses⁷ and composite pulse trains.⁸ Pines et al.^{7,9} have established that an nk quantum selective excitation sequence ($k = 0, \pm 1, \pm 2, \dots$) can be constructed by repeating an appropriate sequence with a phase increment $2\pi/n$ between repetitions:

$$\begin{aligned} \varphi = 0 \quad \varphi = 2\pi/n \quad \varphi = 4\pi/n \quad \varphi = 2(n-1)\pi/n \\ [p_1 \dots p_q] [p_1 \dots p_q] [p_1 \dots p_q] \dots [p_1 \dots p_q] \end{aligned}$$

The pulse sequences $[p_1 \dots p_q]$ employed in each section of the sequence can be nonselective; however, only certain sequences are effective in efficiently generating the desired orders of MQC. Sequences involving several thousand cycled pulses have been explored.^{7,9} An upper limit on the length of the excitation sequence is set by relaxation processes in the spin system. Effective phase-cycled excitation sequences must generate MQC efficiently and compensate for the effects of imperfect rf hardware and pulses.

4 DETECTION OF MULTIPLE QUANTUM COHERENCES

The frequencies of MQCs are obtained indirectly using two-dimensional NMR sequences whereby the multiple quantum frequencies modulate the observable single quantum spectrum. The two-dimensional spectrum contains multiple quantum frequencies in F_1 and single quantum frequencies in F_2 . The frequencies of the multiple quantum spectrum are most conveniently obtained as F_1 projections from the two-dimensional spectrum.

It is not necessary to acquire an entire two-dimensional data set to obtain the multiple quantum frequencies. MQ spectra can be obtained by acquiring a single point in t_2 (at $t_2 = 0$ or some other value) and then transforming the resulting one-dimensional sequence of points as a function of t_1 . In theory, the FT of the $t_2 = 0$ row of a two-dimensional data set is identical to the F_1 projection of the entire two-dimensional data set.¹⁰

If the MQ preparation sequence does not perfectly select coherences from an individual MQ order, then the MQ spectrum detected will be a complex superposition of subspectra from the various MQCs excited. There are several methods available to filter or separate the MQ spectra of various orders.

4.1 Order Selective Detection

4.1.1 Dependence on Resonance Offset

n Quantum coherence evolves n -fold more rapidly during the t_1 evolution period of the MQ experiment than does single quantum coherence. If the single quantum spectrum is centered at a frequency approximately $\Delta\omega$ from the rf transmitter, transitions in the n quantum spectrum are centered at a frequency $n\Delta\omega$. With nonselective excitation, multiple quantum spectra are separated by $\Delta\omega$ and by judicious selection of the transmitter offset, the spectra of various multiple quantum orders can be cleanly separated (Figure 3) in the frequency domain.

The main disadvantages of using transmitter offsets to separate various orders of MQC are: (i) offset frequencies of 10–30 kHz are often required to obtain clean separation of the coherence orders and the large offset results in nonuniform rf distribution and homogeneity across the spectrum; and (ii) for a nonselective experiment where all orders of coherence (up to $\pm N$ orders in an N -spin system) are detected, the total sweep width required in F_1 is prohibitively large. The F_1 sweep width is approximately $N \cdot SW$, where SW is the approximate spectral width of any of the orders of coherence in the spin system; SW may be 100–300 kHz and necessarily gives rise to poor digital resolution.

4.1.2 Time Proportional Phase Incrementation

Time proportional phase incrementation (TPPI) enables the separation of spectra of various coherence orders. If the phase of the excitation radiation is incremented by $\Delta\phi = \Delta\omega \cdot \Delta t_1$ each time that t_1 is incremented by Δt_1 , the n quantum spectrum is centered at a frequency $n\Delta\omega$ from the transmitter in the two-dimensional MQ NMR spectrum. MQ orders are separated in frequency by $\Delta\omega$ in the same fashion as if an offset had been employed.

4.1.3 Order Selective MQ Filtration Using Phase Cycling

Order selective detection of the spectrum of a desired order n is achieved by coadding $4n$ FIDs at each value of τ_1 with the phase of the preparation rf radiation (φ_1 in Figure 2) incremented from $2\pi/4n$ to 2π in steps of $2\pi/4n$ with the receiver phase (φ_3 in Figure 2) incremented by $\pi/2$ at each step.¹¹ Two-dimensional Fourier transformation over τ_1 and τ_2 affords a two-dimensional spectrum which has the MQ

Figure 3 The separation of MQ spectra by employing a transmitter offset: ^1H spectrum of 2-methylthiophene aligned in a liquid crystalline solvent. The spectrum was acquired with the pulse sequence shown in Figure 2 with the transmitter offset approximately 20.7 kHz from the center of spectrum. The full spectrum is symmetrical about $F_1 = 0$ and only half of the spectrum is shown. Frequencies in the MQ spectrum are obtained from an F_1 projection of the two-dimensional data set

frequencies of the desired order of MQC in F_1 and the MQ filtered single quantum spectrum in F_2 .

4.1.4 Coherence Echo Filtration

Order selective detection of the spectrum of a desired order n has been achieved by exploiting the phase properties of MQC transfer echoes. An additional (fixed) period d_e is inserted in the MQ pulse sequence, prior to the mixing pulse of the MQ pulse sequence (Figure 4). The delay d_e results in the MQCs evolving beyond the normal τ_1 period and coherence transfer echoes of the n quantum coherences

maximize in the detection period at nd_e .¹² Different coherence orders give rise to echoes which maximize at different times in the detection period. The spectra derived from individual orders of coherence can be obtained by selecting a detection window to coincide with the maximum signal of the desired order of coherence.

4.1.5 Use of Magnetic Field Gradients

Order selective detection of the spectrum of a desired order n has been achieved by using field gradients.¹³ A field gradient pulse of amplitude g is applied at the end of the MQ evolution

Figure 4 Pulse sequence for selectively observing MQC transfer echoes

period, prior to the mixing section of the MQ pulse sequence (Figure 5). A refocusing gradient of amplitude ng immediately after the mixing sequence selects only signals from the n -quantum spectrum.^{12a, 14}

4.1.6 Phase Sensitive MQ Spectra

A disadvantage of most simple mixing sequences which convert MQCs to detectable single quantum coherence is that the detectable single quantum spectrum has both absorption and dispersion components. As spin systems become larger, the single quantum spectrum degenerates to a mass of overlapping resonances, and any mixing sequence which results in signals of differing phase causes signal cancellation. In larger, more complex spin systems, the single quantum spectrum becomes weaker and inherently more difficult (or impossible) to detect. Pines et al.¹⁵ have developed a general class of MQ experiments where the MQ preparation sequence is matched with a mixing sequence (a time reversal sequence) to give a single quantum spectrum which is in-phase. There are a number of matched preparation/mixing sequences and these have been used to observe high-order MQ spectra, including those in solids.

Another consequence of simple MQ sequences is that the MQ spectra obtained are obtained as spectra that cannot be phased. Most MQ spectra which have been recorded from samples dissolved in liquid crystalline solution have been transformed as magnitude spectra. Using appropriately matched preparation and mixing sequences, pure absorption spectra

have been recorded,^{2b, 16} and these show improved sensitivity and resolution compared with corresponding magnitude spectra.

5 METHODS OF SPECTRAL ANALYSIS AND SPECTRAL SIMULATION

The energy levels of an n -spin system can be calculated if the dipolar coupling constants D_{ij} , scalar coupling constants J_{ij} , chemical shifts ν_i , and quadrupolar coupling constants q_{ij} are known. The energy levels are grouped into manifolds according to their Zeeman quantum number (M) and irreducible symmetry representations. m Quantum transitions occur between energy levels of the same symmetry where $\Delta M = m$. The frequencies of MQ transitions are not difficult to calculate and the frequencies in experimental MQ spectra have been fitted iteratively to calculated frequencies using modifications of LAOCOON type¹⁷ computer algorithms. The calculation of the correct intensities of MQ transitions is more demanding since the transition intensities are a complex function of the specific pulse sequence used to generate the spectrum. Transition intensities in MQ spectra derived from a simple three-pulse sequence (Figure 2) have been estimated using a statistical approach whereby all symmetry-allowed transitions are assumed to be equally excited. Averaging over a range of d_1 values, the integrated intensity per order decreases as ΔM increases, but the average intensity per transition increases as ΔM increases.^{3b} The estimation of transition intensities in MQ spectra has been extended to excitation sequences involving order selective composite pulse excitation, and the calculations provide a reliable means for theoretically optimizing the efficiency of the excitation sequence.¹⁸

6 APPLICATIONS OF MQ NMR TO SAMPLES DISSOLVED IN LIQUID CRYSTALLINE SOLVENTS

6.1 Structural Studies

In the spectra of compounds dissolved in liquid crystalline solution, dipolar interactions between nuclei are not averaged to zero and the spectra can, in principle, be analyzed to obtain values for the dipolar coupling constant D_{ij} between each pair of nuclei (i and j) in the solute spin system. Since the D_{ij} are inversely proportional to the cube of the internuclear distances r_{ij} [equation (3)], the relative positions of the nuclei in the spin system can be determined and the shape of the molecule as well as its average orientation in the magnetic field can be deduced, providing enough independent D_{ij} values can be measured. For a system of coupled $I = 1/2$ nuclei, the transition frequencies in the MQ spectra are determined by the dipolar coupling constants, the scalar coupling constants, and the chemical shifts of the nuclei. In theory, the spectra of order $n - 1$ and $n - 2$ contain sufficient transitions to measure all the dipolar coupling constants and chemical shifts in an n -spin system:

$$D_{ij} = -(h\gamma_H^2/4\pi^2)S_{ij}/r_{ij}^3 \quad (3)$$

Figure 7 Experimental (upper) and simulated (lower) multiple quantum spectra of 1-bromonaphthalene aligned in liquid crystalline solution. Experimental spectra were acquired with chemical shift refocusing in F_1 and spectra were symmetrized about $F_1 = 0$. Simulations assume all transitions have the same intensity. Reproduced by permission of Academic Press from Reference ^{20a}

where γ_H is the proton magnetogyric ratio, r_{ij} is the internuclear distance between protons i and j , and S_{ij} is the order of the internuclear vector between i and j .¹⁹ There have been only a few studies in which the geometry of a spin system has been established using MQ NMR.

6.1.1 Structure of Rigid Molecules: Structure of 1-Bromonaphthalene

1-Bromonaphthalene has a proton spin system containing seven nonequivalent spins. In liquid crystalline solution the ^1H NMR spectrum contains more than 3000 transitions (Figure 6).²⁰ The five and six quantum spectra have been recorded and solved simultaneously (Figure 7) to give values for the 21 independent dipolar coupling constants, and from the D_{ij} values the geometry of the planar seven spin system was determined.²⁰

6.1.2 Chain Mobility in *n*-Hexane- d_6

MQ NMR has been employed to study chain mobility in alkanes dissolved in liquid crystalline solution. Drobny^{2b} has reported the MQ spectra of *n*-hexane- d_6 (deuterated in the terminal methyl groups) dissolved in a nematic solvent. MQ spectra were recorded and the high quantum spectra (six and seven quantum) analyzed to give dipolar couplings. The six quantum proton spectrum contains 36 transitions and the seven quantum spectrum contains four transitions, as expected for an eight proton spin system with C_{2h} symmetry. The best fit of theoretically generated MQ NMR spectra to the experimental spectra was obtained with a model where only the minimum energy conformations of the alkane chain were appreciably populated.

6.1.3 Structure of 4-Cyano-4'-*n*-pentylbiphenyl

4-Cyano-4'-*n*-pentylbiphenyl is a nematic liquid crystal at room temperature. The five, six, and seven quantum MQ NMR spectra of the eight proton spin system of a partially deuterated compound (with the pentyl side chain completely deuterated) have been analyzed to give the interproton dipolar couplings in the biphenyl core of the molecule.²¹ The best match between the experimental and simulated MQ NMR spectra were obtained when the biphenyl system was not planar, but when there was an angle of about 32° between the linked phenyl groups.

6.2 Counting Spins in Clusters

In MQ NMR, individual spins become correlated with each other over time through their dipolar couplings. The rate at which MQCs develop is a complex function of the coupling constants present in the spin system. In solids, where the distribution of dipole coupled spins is effectively infinite, the correlations between spins develop in a monotonic fashion. As time progresses, more spins can absorb more quanta and high order MQC can be generated.²² In systems where there are effectively isolated clusters of spins (e.g. liquid crystals, molecules dissolved in liquid crystalline phases, and polycrystalline solids) the time development of MQC is

Figure 8 The effective system size $N(\tau)$ as a function of the preparation time τ for the liquid crystal 4-cyano-4'-heptylbiphenyl. After an induction period of approximately $1000 \mu\text{s}$, $N(\tau)$ levels off to a value of 21, reflecting the number of spins in the isolated molecular cluster. Reprinted by permission of the American Chemical Society from Baum and Pines²²

interrupted and the system can only support MQC up to the size of coupled spin clusters. In the 21-spin system of the liquid crystal 4-cyano-4'-heptylbiphenyl, the effective spin system size increases to a maximum of 21 spins as the preparation time for MQC increases (Figure 8).

The rate of MQC development in a mixture of liquid crystalline materials has also been used to identify and observe distinct subsections of molecules comprising the liquid crystals. Separate MQ signals were observed for effectively isolated spin pairs (phenyl rings) and weakly coupled multispin clusters (alkyl tails)²³ in a mixture of 4-cyanophenyl 4'-butylbenzoate and 4-cyanophenyl 4'-heptylbenzoate.

6.3 Measurements of Diffusion

MQC has been used to extend the normal NMR spin echo measurement of diffusion. In typical spin echo experiments, molecules are labeled by their position in a magnetic field gradient after an initial rf pulse and diffusion is measured by monitoring the amplitude of the spin echo following a second pulse. MQ NMR spectroscopy exploits the fact that n quantum coherence dephases n -times more quickly than does single quantum coherence, so higher quantum coherences are significantly more sensitive to diffusion.

Martin et al.²⁴ measured the diffusion of dichloromethane (CH_2Cl_2) in various liquid crystal solvents by following the decay of the double quantum coherence. In measurements of the diffusion of benzene in a nematic liquid crystal, Zax and Pines²⁵ used a pulse sequence [Figure 9(a)] to excite MQC nonselectively and then selectively monitored the decay of the coherence echo of the $n = 1$ to $n = 6$ orders of coherence following field gradient pulses. The amplitude of echo decay for all orders of coherence was fitted to a modified Stejskal-Tanner equation²⁶ (Figure 9), thus verifying that the rate of echo decay is proportional to n^2 .

6.4 Molecular Motion and Relaxation

The spectral densities of molecule motion $J_q(\omega)$ are usually estimated by simultaneously analyzing a combination of

Figure 9 (a) Pulse sequence for an NMR pulsed field gradient experiment. (b) Normalized echo amplitudes plotted against the gradient pulse timing parameter $[\delta^2(\Delta - \delta/3)]$ of the Stejskal–Tanner equation.²⁶ (Reproduced by permission from D. Zax and A. Pines, *J. Chem. Phys.*, 1983, **78**, 6333)

relaxation measurements. Spectral densities may be measured from the decay of MQC and, particularly in $I = 1$ systems where the relaxation mechanism is dominated by the nuclear quadrupole, the relaxation of zero, double, triple and higher order coherences have been used to determine the spectral densities of motion for small deuterated organic molecules (CDCl_3 ,²⁷ $\text{D-C}\equiv\text{C-C}\equiv\text{N}$,^{27b}, CD_2Cl_2 ,²⁸ and $\text{CD}_3\text{-C}\equiv\text{N}$,²⁹) dissolved in liquid crystalline solution. The relaxation of the two and three quantum resonances of ^{23}Na ($I = \frac{3}{2}$) and the four and five quantum resonances of ^{17}O ($I = \frac{5}{2}$) have been measured in lyotropic liquid crystals.³⁰

6.5 Heteronuclear MQC

Heteronuclear MQC (HMQC) (coherence involving spins of different type, e.g. $^1\text{H}/^2\text{H}$ or $^1\text{H}/^{15}\text{N}$) have been used to study molecules in liquid crystal solution. Minoretti et al.³¹ have demonstrated that there is a significant sensitivity advantage when the MQCs of a relatively insensitive nucleus (e.g. ^2H) can be detected indirectly by observing ^1H nuclei coupled to the heteronuclear spin system.

1 INTRODUCTION

There are strong motivations for pursuing solid state NMR of protons, namely the inherently good sensitivity and the possibilities for study of hydrogen bonding via chemical shifts. Despite its enormous potential, solid state NMR of protons in biomolecules has had surprisingly few applications in comparison with other high-resolution NMR methods for studying biological macromolecules. In this article we discuss experimental solutions to the problem of spectral resolution and the analysis of spectra for chemical information. Although essentially all of the successful measurements of chemical shift and shift anisotropy were obtained on simple crystalline solids we also discuss possible future applications in structural biology.

2 APPROACHES TO NARROWING PROTON RESONANCES

Producing narrow proton linewidths is the most significant challenge to solid state proton NMR. For the case of a typical rigid organic solid, ^1H NMR spectra obtained without sample spinning or with moderate speed sample spinning show very broad lines, on the order of a few tens of kilohertz. Narrowing of these lines by the technique of combined rotation and multiple pulse spectroscopy, CRAMPS,^{1–4} or by dilution of the protons^{5–7} has been demonstrated in crystalline small molecules. These methods have provided the means to study hydrogen bonding and proton exchange in solids, but practically no high-resolution solid state ^1H NMR applications

to macromolecules have been reported. In contrast to rigid organic solids, solids with high molecular mobility such as lipids and membrane structures often provide well-resolved ^1H NMR simply by Bloch decay acquisition with slow magic angle spinning.^{8–11}

The CRAMPS method is the most common experimental approach to achieving high-resolution ^1H spectra of materials in the solid state. It has been used in interesting applications of chemical analysis,^{12–15} and probably has the most potential for general studies of amorphous biological solids. Proton NMR linewidths obtained by CRAMPS or magnetic dilution can be as low as 0.2 ppm, which could be sufficient to separate the typical functional groups found in a protein but of course would never be adequate for site-specific assignments of even a small peptide. Highly crystalline compounds typically produce the narrowest lines, while compounds with some amorphous character produce somewhat broader lines.¹⁴ Macroscopic susceptibility due to the shape of the microcrystal presumably contributes to the linewidth, and specific anisotropic bulk susceptibility effects in aromatic systems have been discussed.¹⁴

An alternative method that has been little pursued to date is the detection of deuterons during magic angle spinning (MAS). With this approach resolution comparable to that of CRAMPS or dilution can often be obtained without special effort,^{16,17} and spectral overlap can be avoided by utilizing selective labeling. Considerable spectral intensity is squandered into spinning sidebands, so application of methods to fold the sidebands together is important. On the other hand, the quadrupolar constants and dynamic information normally obtained from static ^2H NMR can be derived from the sideband patterns in these spectra. Several reports of cross polarization between deuterium and protons have appeared.^{16,18}

In the following discussion we will focus more on CRAMPS than the other two approaches because of the much larger existing literature and the far fewer complications with sample preparation. We illustrate the typical appearance of CRAMPS spectra of simple organic biological solids with a series of CRAMPS spectra of amino acids and dipeptides in Figure 1; some of these samples have also been characterized by measurement of dilute protons⁶ or by spinning ^2H spectra.¹⁷ It is apparent from Figure 1 that the linewidths are significantly below 1 ppm in every case and the spectra allow resolution

Figure 1 The 200 MHz BR-24 spectra of crystalline amino acids (as indicated). Pulse length was $1.3\ \mu\text{s}$ with a τ value of $2.3\text{--}3.0\ \mu\text{s}$ and spinning speeds of $1.0\text{--}1.5\ \text{kHz}$. Sixteen transients were accumulated. Glu = glutamic acid, Asp = aspartic acid, Ala = alanine, Arg = arginine, Lys = lysine, Gly = glycine

Figure 2 Typical CRAMPS spectra of biological molecules, measured at 187 MHz with the BR-24 pulse sequence.¹⁹ Top: amylopectin; middle: γ -globulin; bottom: coconut oil. Spectra were acquired with MAS spinning speed of 1–2 kHz, pulse width = 1.0–1.2 μ s, τ = 3.0 μ s, repetition time 1.7 s

of one chemical classification from another. For aliphatic or aromatic protons the chemical shifts are comparable to those known from solution state experiments, that is –1 to 2 ppm for methyl groups, 1–3 ppm for methylene, 3–5 ppm for methine, and 6–8 ppm for aromatic protons. Unlike solution spectroscopy, in solid state experiments observing acid and other exchangeable protons is possible, and in particular for the case of carboxylic acids the range in typical shifts is quite a lot broader than the linewidths. The amine and many of the other N–H functionalities are often around 7–8 ppm, while imidazole protons and structural water protons and carboxylic acids can be found at a broad range of shift values depending on hydrogen bonding, with strongly hydrogen-bonded groups being significantly deshielded (10–20 ppm). The chemical shifts and lineshapes for resonances in hydrogen bonding groups are discussed in detail in the following sections.

Typical ^1H CRAMPS spectra of other biological materials are also exhibited in Figure 2.¹⁹ The carbohydrate spectrum (top) is dominated by methine and hydroxyl protons. The protein spectrum (middle) shows contributions from methyl, methylene, methine, amine, and other groups but is largely unresolved. A methylene resonance at 1.3 ppm dominates the lipid spectrum (bottom). As noted above, MAS-only spectra of lipids provide good ^1H resolution. Proton linewidths of lipids and highly mobile materials are often narrower in MAS-only spectra than in CRAMPS spectra¹⁹ due to pulse imperfections in the multiple pulse sequence.

3 INFORMATION FROM THE LINESHAPE

All three detection methods show certain potentially confusing effects that deserve special comment. As has been reported previously^{1,20} dynamic processes can interfere with the CRAMPS detection of groups undergoing motion if the correlation times are comparable to the pulse width, the multiple pulse cycle time, or to the sample spinning speed. This effect is often seen at room temperature in the form of missing amine resonances. Amine groups enact a three-site hopping motion on the microsecond timescale near room temperature since they have activated barriers in the range of 30 kJ mol^{–1}. This motion has been previously characterized by wide-line ^1H T_1 measurements²¹ but not by lineshape methods. Such amine lines that are broad or undetected near room temperature

Figure 3 The 200 MHz BR-24 spectrum of L-aspartic acid at various temperatures. Note that the amine resonance at 7.7 ppm disappears near room temperature (RT) due to the microsecond correlation time for the amine's threefold hopping rate. This behavior is quite common for amine groups although the critical temperature is variable

are readily detected at temperatures above 70 °C or below –100 °C in typical cases. Figure 3 shows variable temperature ^1H CRAMPS spectra of L-aspartic acid in which the amine line at 7.7 ppm illustrates this effect. Other effects on the lineshapes as a function of temperature are often observed, and analysis of these lineshapes by explicit simulation would be informative but has not yet been accomplished. Other than the amine rotation, common local motions in proteins rarely result in loss of signal because the rates are not on the microsecond timescale near room temperature. The ^2H MAS spectra exhibit lineshape and intensity effects for amines in a comparable temperature range: here the sampling rate of data collection is usually in the submegahertz range so again motions in the microsecond range interfere with detection. Proton spectra of magnetically diluted (deuterated) samples detected using Bloch decay during MAS would presumably show lineshape effects due to much slower motions, approximately on the millisecond timescale. Hence detection of sharp spectra due to the amine peaks is usually straightforward by ^1H MAS spectra. In all three methods interpretation of line intensities is quite unreliable because of all of these lineshape effects and/or the uncertainties involved in the extent of chemical incorporation of deuterium.

Protons that are directly bound to nitrogens often exhibit a lineshape that is obviously affected by the incomplete averaging of dipolar coupling to the ^{14}N resulting from the fact that the strongly quadrupolar ^{14}N is not in the high-field limit. These effects are most clear in lower field spectra²² and can be seen in the 200 MHz high-temperature CRAMPS spectrum of aspartic acid (Figure 3) but also have been seen in well-resolved high field spectra.⁵ They offer the possibility of characterization of the bonding geometry and the quadrupole parameters for the nitrogen from the ^1H lineshapes²² as has been done for ^{13}C lineshapes for $^{13}\text{C}^{14}\text{N}$ pairs.^{23–26}

4 HYDROGEN BONDING: CHEMICAL SHIFT AND HYDROGEN EXCHANGE

For protons that participate in hydrogen bonding, there are well-known correlations between the shielding of the ^1H isotropic chemical shift, the ^1H shielding anisotropy, the ^2H coupling constant, and hydrogen bonding distances^{1,27–29} for

Figure 4 The ^1H chemical shifts of the amino acids in Figure 1 plotted against their O...O distances as indicated by crystallography. Filled circles show proton chemical shifts derived from our data, as shown in Figure 1; crystal structures for these compounds can be found in Rao,⁴⁰ Eggleston and Hodgson,^{41–43} Derissen et al.,⁴⁴ Bhat and Vijayan,⁴⁵ Sequeira et al.,⁴⁶ and Hamilton and Parthasarathy.⁴⁷ The open circles are from previous measurements in Harris et al.¹

small crystalline compounds. Quantification of hydrogen bonding is of great interest for studies in structural biology because of the role in recognition and conformational preferences. Solid state NMR could potentially be far more sensitive to details of hydrogen bonding and ionization states than crystallography. The chemical shifts for the acid protons for carboxyl groups in amino acids (shown in Figure 1) correlate with hydrogen-bonding length and this plot is shown in Figure 4 in filled circles. In comparison with previous measurements¹ which are entered here as open circles, our data encompass a rather restricted range because of the limited scope of compounds that are both relevant as model systems for proteins and sufficiently characterized. Clearly there is some scatter in the data but there is also a general trend that reproduces previous correlations.

Anisotropy of the proton shielding has been reported in a variety of solids with very simple structures; a thorough compilation and reviews are available.^{30–32} Many of these values were obtained from static multiple pulse measurements on either single crystals or powders or from rotation plots of the deuterium signal of a single crystal. The shielding anisotropy, $|\Delta\sigma| = |\sigma_{\perp} - \sigma_{\parallel}|$, is quite narrow (about 4–7 ppm) for alkyl or aromatic protons (except for methyl groups which are 1–2 ppm), but for some ionizable protons the anisotropy is more pronounced, with values of approximately 17 ppm for amides and 16–30 ppm for acids, alcohols, and water, but only about 5 ppm for amines. A detailed analysis of tensor values and orientations would presumably be useful in studying nonbonded interactions but is probably not possible in biological solids in the near future. Many complications affect the CSA measurements by CRAMPS, such as residual homonuclear and heteronuclear dipolar interactions, molecular motion, and chemical shift scaling. Magnetically dilute protons in organic solids give rise to spinning sidebands during low-speed MAS, and when the percentage of hydrogens that are replaced with deuterons is approximately 99% or larger these sidebands appear to be dominated by CSA effects (A. McDermott, unpublished).

A point of specific interest in solid state studies of hydrogen bonding is the fact that hydrogen bonds can have

profound effects upon reactivity in biological catalysis. For example, acid–base chemistry or proton mobility in the solid state is presumably strongly affected by local nonbonded interactions, a point which is relevant in many enzyme mechanisms. The geometric preferences of hydrogen bonds and the specific control of reactivity can be probed in the solid state studies since particular networks are arrested on an experimentally accessible timescale. Protons that participate in typical thermally driven and near-reversible exchange processes in proteins are found on the ‘ionizable’ hydrogen bonded groups such as carboxyl, imidazole, water, amine, alcohol, and guanidinium. The typical exchange timescales of microseconds to hours are presumably sensitive to the specific hydrogen-bonding geometry in a way that might be predicted by *ab initio*³³ or semiempirical methods. A systematic study of chemical exchange processes as a function of geometry in structurally characterized solids by NMR would help to clarify the theory of proton exchange.

Recent advances in ^1H NMR of deuterated simple model compounds for proteins show that such measurements of exchange processes are possible. Variable temperature two-dimensional (2D) methods applied to one example of a low symmetry hydrogen-bonded network of carboxylic acids and crystallographic water molecules demonstrated unambiguously that a proton is transferred between water and a carboxyl group⁶ in an activated process with a barrier of 37 kJ mol^{−1}. Additional measurements will be necessary for the purpose of creating a database that correlates rates of exchange with structural features.

5 2D CORRELATION WITH CARBON

The more ambitious goal of utilizing ^1H NMR for detailed structural analyses of amorphous solid materials or complex solid state macromolecules is not practical without addressing the problem of resolution of one ^1H resonance from the others of the same chemical functional group. The approach taken by solution NMR spectroscopy to correlate the ^1H resonance with nearby or attached heteronuclei is applicable in solids as well. The ^{15}N or ^{13}C NMR spectra in the solid state are considerably broader than solution spectra but nonetheless often allow distinction of a handful of selectively labeled residues. Two important classes of 2D H–X experiments for solid state NMR of H–X pairs are dipolar chemical shift correlation methods or ‘DIPSHIFT’³⁴ for determination of the bond distance to a great accuracy in a spin pair and heteronuclear correlation methods or ‘HETCOR’,^{35–37} which maps the chemical shifts of the X nucleus to nearby protons via the dipolar coupling. The latter is clearly the experiment of choice when more than one proton connected with the heteronucleus of interest should be resolved and rather approximate distance information will suffice. Our recent work with HETCOR and modified versions of the pulse sequence demonstrate the observation of longer H–X distances including C–O...H hydrogen bonds which appear as weak cross peaks. Rotor-synchronized transfer sequences have been used to increase the range of H–X distances probed by this method.³⁸ As an example, the HETCOR spectrum of alanyl aspartic acid is shown in Figure 5. In particular the ^1H – ^{13}C correlation peaks between the carboxyl groups around 170 ppm in the ^{13}C dimension and the acid proton near 12.5 ppm in the

Figure 5 Rotor-synchronized HETCOR spectrum of alanyl aspartic acid at 200 MHz and room temperature. Magnetization transfer was accomplished by 2.5 WIM-24 cycles per rotor period during four sequential rotor periods. The 90° pulse lengths were $3.2 \mu\text{s}$ for both channels. Experimental repetition time was 1.7 s. Data matrix was 80×512 points zero-filled to 512×512 with 20 Hz linebroadening in D_2 and a Kaiser window applied to D_1 . SSB = spinning sidebands

^1H dimension are indirectly connected pairs; several of the ^{13}C resonances show more than one ^1H cross peak.

Since essentially all of the resolution in the HETCOR experiment comes from the heteronuclear dimension, it is probably worthwhile to reiterate the virtues of such a 2D experiment in comparison with a one-dimensional (1D) heteronuclear measurement. Although detailed information about hydrogen bonding is available from heteronuclear NMR, the information from the ^1H shifts is often independent of that obtained from the heteronuclear shift. A case in point is the carboxylate group: the ^1H shift depends on the interaction of the detected acid proton with the nearest hydrogen bond acceptor, while σ_{22} of the ^{13}C shift depends on the distance between the carboxyl oxygen, which acts as a hydrogen bond acceptor, and the nearest proton.³⁹ The 2D HETCOR experiment provides the possibility of identifying the chemical nature of the hydrogen bonding partners to a carbon-containing functional group, even if the partners are water molecules. In a more practical light, we have found the HETCOR experiment to be quite useful in determining or confirming ^{13}C assignments for larger peptides and pharmaceuticals. As for disadvantages, obviously the time investment in such an experiment is enormously greater than that necessary for a 1D heteronuclear experiment. In the 2D spectra interpretation of the proton dimension is subject to similar complications as the CRAMPS experiment. In particular the intensities of the lines depend strongly on the presence or absence of mid-kHz motions.

Some of these issues are well illustrated with the spectrum of natural abundance alanyl aspartic acid. The three carbonyl-type carbons are readily identified by the HETCOR spectrum with one being a protonated carboxyl, one being deprotonated but hydrogen bonded to the protonated carbonyl, and the third being an amide carbonyl with no cross peak to the acid proton.

A strong hydrogen bond between the two carboxyl groups is indicated by both the deshielded acid proton (14 ppm) that was detected in the HETCOR spectrum and the σ_{22} value for the deprotonated carboxyl group (184 ppm) that was determined in 1D low-spinning CP MAS sideband analysis. Moreover the assignment of both the ^{13}C and ^1H dimensions can be verified by comparison of the ^1H shifts in the cross peaks of the carbonyl resonances with those in the methylene/methine region. From such a comparison one could have identified, for example, that the protonated carboxyl is alpha to a methylene while the deprotonated carboxyl is alpha to a methine. The fact that good sensitivity was obtained for a naturally abundant dipeptide implies that moderate-sized proteins can be studied by this approach if they are selectively labeled.

6 CONCLUSIONS

The long-established relationships between proton shift and hydrogen-bonding distances were confirmed in the more restricted data base of amino acids and peptides. Utilization of these 1D CRAMPS methods for proteins is unlikely because of the 0.3–1 ppm linewidths. These measurements might be of use in more complex solids if the spectrum is separated into two dimensions using correlations to attached heteronuclei in the HETCOR experiment. Demonstrations of HETCOR spectra on small peptides with naturally abundant ^{13}C demonstrate the requisite sensitivity for biological work and indicate the potential for measuring hydrogen bonding parameters and confirming assignments.

1 INTRODUCTION

All experiments are imperfect. Advances in the engineering and design of NMR spectrometers mean that NMR experiments have steadily improved in quality over the last 50 years, and are certainly closer to perfection than many other types of spectroscopic measurement, but nevertheless all NMR measurements carry internal evidence of the shortcomings of the experimental equipment and techniques used. Some sources of imperfection are inevitable: any electronic measurement that takes place above absolute zero contains random noise originating in the thermal motion of charge carriers. Many other sources could be avoided in an ideal NMR instrument: line broadening or spinning sidebands caused by static magnetic field inhomogeneity, difference artifacts caused by instabilities in field-frequency ratio, and phase errors caused by impure radiofrequency sources. One feature shared by all the members in this list is that they affect all the signals in a spectrum in the same way: each can be described as a multiplication of the expected free induction decay by some sort of error function. It is therefore possible in principle to correct for the effects of these sources of imperfection by using prior knowledge of the form expected for a given line in the spectrum. This is the basis of reference deconvolution,¹ in which the experimental spectrum is deconvoluted with the experimental form of a reference signal and reconvoluted with the theoretical ideal form, to yield a spectrum in which instrumental distortions are suppressed for all signals. In keeping with its original use for the correction of lineshapes, the method is often referred to by the acronym FIDDLE (Free Induction Decay Deconvolution for Lineshape Enhancement), although strictly it is the experimental spectrum, rather than the free induction decay, that is deconvoluted.

The basic principles of reference deconvolution are illustrated in Figure 1, which uses data from a 300 MHz proton experiment in which the homogeneity of the static field was deliberately perturbed. The spectrum contains a signal from acetone which should be a simple singlet, but which in common with all the other signals in the spectrum shows severe

lineshape errors and spinning sidebands because of the combination of poor B_0 homogeneity and sample spinning. If the Fourier transform of the raw experimental free induction decay, Figure 1(b), is treated by zeroing all the spectrum apart from the region containing the acetone signal, inverse Fourier transformation of this windowed spectrum will yield a time-domain signal which is that component of the original free induction decay attributable to the acetone reference signal. This time-domain acetone signal is the product of the signal that would have been recorded by a perfect instrument, multiplied by a complex time-dependent envelope function which describes the modulation of the signal by the spatially and temporally varying magnetic field experienced by different parts of the sample, and supplemented by a background of random noise.

The ideal form of the signal expected from theory is straightforward: in the frequency domain, a Lorentzian line centered on the acetone chemical shift, and in the time domain, a complex exponential that rotates at the acetone chemical shift and decays exponentially. It is thus possible both to deduce the form of the error modulation experienced by the experimental signal, and to produce a spectrum corrected for its effects, by taking the complex ratio of the theoretical and experimental forms of the reference signal. Multiplying the original experimental free induction decay by this time-dependent complex ratio yields a corrected signal, shorn of the unwanted modulation, which can be Fourier transformed to yield a corrected spectrum with ideal lineshapes (Figure 1b). The price paid is a small increase in the complexity of data processing, and an increased (and non-white) noise background.

Reference deconvolution is not limited to the correction of lineshape errors: many different instrumental errors are multiplicative in the time domain and hence susceptible to

Figure 1 Schematic illustration of simple reference deconvolution. Deconvoluting the raw experimental spectrum (a) with the acetone lineshape contained in the arrowed frequency range and reconvoluting with a 1 Hz wide Lorentzian gives the corrected spectrum (b), in which signals have essentially perfect lineshapes. (Adapted from 'Progress in Nuclear Magnetic Resonance Spectroscopy', Vol. 31, G. A. Morris, H. Barjat and T. J. Horne, Reference Deconvolution Methods, pp 197–257, Copyright (1997), with permission from Elsevier Science)

correction in this way. Examples include changes in receiver gain, field-frequency ratio, receiver phase, and many of the sources of t_1 -noise in 2D NMR spectroscopy. Unlike other post-processing methods for improving the interpretability of NMR data, such as maximum entropy reconstruction or linear prediction, reference deconvolution is essentially a linear process. Prior knowledge of the theoretical form of the reference signal is used to allow the experimental signal(s) to be factorized into a corrected spectrum and an experimental lineshape, with no change in the overall information content. This linearity represents both a strength and a weakness. The risk of over-interpretation of the experimental evidence, ever present with nonlinear methods, is small. However, reference deconvolution cannot produce corrected data where there is no experimental evidence. The range of experimental imperfections that may be corrected is thus finite: if the time-domain envelope of an experimental signal touches zero, division of the ideal time-domain signal by its experimental form will produce a singularity. In such circumstances there is a choice between restricting the correction of the signal to times before the experimental signal disappears, and invoking nonlinear methods.

2 HISTORICAL BACKGROUND

Experimental spectroscopists frequently use the principle of reference deconvolution implicitly: if a small shoulder appears on one side of an NMR line, the immediate reaction is to check for the same feature elsewhere in the spectrum. If absent, the shoulder represents a real signal; if present throughout, it probably indicates a shimming error and can safely be ignored. Giving this principle quantitative form, numerical fitting of complex multiplets with an experimental lineshape dates back at least to 1966.^{2,3} Reference deconvolution proper has been independently proposed at least four times in different guises, for correcting pulse Fourier Transform FT NMR,^{4,5} correlation NMR⁶ (Reference Lineshape Adjustment, RLSA) and in vivo NMR⁷ (Quantification Improvement by Converting Lineshapes to the Lorentzian Type, QUALITY) data. Although the algorithms proposed differ somewhat in detail, all share the same basic features. In addition to these methods, which seek to use all the experimental information available in the correction process, a variety of less general methods have been proposed which seek to correct just one or two classes of error. Examples include time-dependent phase correction in in vivo experiments using pulsed field gradients,⁸ and phase⁹ or phase and amplitude¹⁰ tracking for t_1 -noise reduction in 2D NMR experiments.

3 THEORY

The basic algorithm described in the Introduction can be quite effective, but in all but the simplest spectra it suffers from a significant disadvantage. In order to obtain the experimental free induction decay for the reference signal alone it is necessary to filter out contributions from all other signals. At first sight this is straightforward; zeroing all but the arrowed reference signal region of Figure 1(a) should have the desired effect. However, in order to obtain the complete time-domain reference signal it is necessary to use both real (absorption

mode) and imaginary (dispersion) mode parts of the raw experimental spectrum. Because the dispersion mode signal falls off only hyperbolically with frequency offset, it is much more difficult to choose a reference region which neither truncates the dispersion mode reference signal nor includes signal from other resonances. The solution is to perform the filtering of the experimental spectrum on the absorption mode signal alone, and reconstruct the missing contribution from the dispersion signal using the Hilbert transform relationship between the two. Provided that the raw experimental free induction decay is zero-filled at least once before Fourier transformation, no net loss of information results.

A practical algorithm for reference deconvolution proceeds as follows. The raw experimental free induction decay $s_e(t)$ is zero-filled once, Fourier transformed and phase corrected to yield an experimental spectrum $S_e(\omega)$. The experimental free induction decay for the reference signal $s_r(t)$ alone may be obtained by taking the first half of the inverse Fourier transform of the windowed spectrum:

$$s_r(t) = \text{FT}^+ [\text{Re}\{S_e(\omega)\}] \prod(\omega_R, \omega_L) \prod(0, t_{\max}) \quad (1)$$

Here FT^+ and FT^- indicate inverse Fourier transformation and Fourier transformation respectively:

$$\text{FT} \pm [A(\omega)] = \frac{1}{2\pi} \int_{-\infty}^{+\infty} A(\omega) e^{\pm i\omega t} d\omega \quad (2)$$

the window function $\prod(a,b)$ is unity between a and b and zero elsewhere, the reference signal (and nothing else) is entirely contained within the frequency range ω_R to ω_L , and $t_{\max}$ is the time for which the experimental free induction decay is recorded. The windowing $\prod(0, t_{\max})$ is necessary because transforming only the real part of $S_e(\omega)$ generates a time-symmetric function consisting of the required signal followed by its reflection. The use of zero-filling before the initial Fourier transformation ensures that no information is lost when this reflection is discarded.

The next step is to calculate the ideal form $s_i(t)$ of the ideal reference signal. This may be done either by direct calculation in the time domain, or by inverse Fourier transformation of the theoretical spectrum; in both cases it is necessary to include explicitly any known satellite signals, isotope shifts etc. The choice of lineshape for the ideal reference signal is critical. The obvious choice, the natural lineshape, is almost always far too ambitious: because most experimental spectra are significantly broadened by field inhomogeneity, setting a target lineshape which is much narrower than the experimental lineshape generally yields unacceptably low signal-to-noise ratio. As with other forms of resolution enhancement, the uninformative limit is an infinitely sharp spectrum with zero signal-to-noise ratio. The solution is to select a target lineshape, typically Lorentzian, Gaussian, or some mixture of the two, which gives a suitable compromise between resolution and signal-to-noise ratio in the corrected spectrum. In general the ideal reference signal can be described as a sum of rotating complex exponentials multiplied by an envelope function $W(t)$:

$$s_i(t) = \sum_{j=1}^n a_j \exp(i\omega_j t) \times W(t) \quad (3)$$

where the summation is over the known components of the reference signal, and $W(t)$ typically has the form

$$W(t) = \exp\left[-\frac{t}{t_e}\right] \exp\left[-\frac{t^2}{t_g^2}\right] \quad (4)$$

with exponential and Gaussian components defined by the time constants t_e and t_g receptively.

The correction function required is then the complex ratio $c(t)$ between the theoretical and experimental reference free induction decays:

$$c(t) = \frac{s_i(t)}{s_r(t)} \quad (5)$$

Since the experimental reference free induction decay is derived from a phase-corrected spectrum (in order to avoid dispersion mode contributions), any frequency-dependent component of the phase correction will have had the effect of giving a small time shift to the time-domain signal. Therefore to ensure exact time correspondence between the full and the reference experimental free induction decays, a time-shifted version $s'_e(t)$ of the former should be produced:

$$s'_e(t) = \text{FT}^+[\text{Re}\{S_e(\omega)\}] \prod(0, t_{\max}) \quad (6)$$

The corrected spectrum is finally obtained by Fourier transforming the product of the time-shifted full experimental free induction decay and the correction function $c(t)$:

$$S_c(\omega) = \text{FT}^- [s'_e(t)c(t)] \quad (7)$$

The complete process is summarized in Figure 2. The raw experimental free induction decay (a) is zero-filled, Fourier

transformed and phase corrected (b), and then inverse Fourier transformed with (d) and without windowing to yield the reference free induction decay (c) $s_r(t)$ and the time-shifted (phase-corrected) full free induction decay (i) $s'_e(t)$. The ideal reference signal (e) $s_i(t)$ is calculated either directly or by inverse Fourier transformation of the ideal spectrum (f). Finally the time-shifted signal (i) is divided by the experimental reference signal (c) and multiplied by the ideal reference signal (e) to give the corrected free induction decay (g), which may be transformed to give a corrected spectrum (h) $S_c(\omega)$.

Not all experimental spectra contain a suitable singlet reference signal. There is a fundamental difficulty in using reference signals which are simple multiplets, in that such signals contain zeroes in the time domain. It is however still possible to use such signals in spectra with good signal-to-noise ratio, by interpolating the correction function $c(t)$ over the gaps in the experimental data. Although this compromises slightly the linearity of the process, in practice the extra information generated is a very small proportion of the whole, and the interpolation works well. The principal problem is the need for the ideal reference signal to be very accurately characterized, as visible artifacts can result from errors of just a few MHz in coupling constant or a fraction of a percent amplitude asymmetry. Fortunately the effects of such errors are simple and predictable (spurious sidebands at harmonics of the multiplet splitting), and iterative minimization of such sidebands can be used to refine the form of the ideal signal. Provided care is taken, very good results can be obtained with doublet reference signals.¹¹

Reference deconvolution is not restricted to one-dimensional spectra, but different multidimensional experiments may

Figure 2 Schematic summary of a practical algorithm for reference deconvolution. (Reprinted from 'Progress in Nuclear Magnetic Resonance Spectroscopy', Vol. 31, G. A. Morris, H. Barjat and T. J. Horne, Reference Deconvolution Methods, pp 197–257, Copyright (1997), with permission from Elsevier Science)

require different implementations. The discussion which follows concerns the application to 2D NMR, but similar considerations apply to all multidimensional NMR experiments. Reference deconvolution for the simple correction of lineshape errors can be applied to any 2D experiment by using a correction function derived from a conventional 1D experiment. The same correction function is applied to every experimental free induction decay, correcting the lineshape in F_2 ; where appropriate, the same correction can be used in F_1 . A much more powerful use of reference deconvolution in 2D NMR is for the correction of t_1 -noise, but here two complications intrude. The first is that reference deconvolution only corrects for instrumental errors which affect all signals equally; in 2D NMR, this can effectively limit reference deconvolution to correcting a single coherence transfer pathway. The second problem is that reference deconvolution cannot be used where there is no reference signal, preventing (or at least greatly complicating) its application to experiments in which the reference signal is amplitude modulated as a function of t_1 .

Reference deconvolution has been applied very successfully to two different classes of 2D experiment: those in which t_1 -noise is dominated by a single unwanted pathway (e.g., HMBC (heteronuclear multiple bond coherence)), and those in which pulsed field gradients are used to ensure that only a single coherence transfer pathway survives (e.g., gradient enhanced COSY (correlation spectroscopy), gradient NOESY (nuclear Overhauser effect spectroscopy)). In the former case, the normal phase cycle is split into two halves in which the unwanted signals are of opposite phase, and reference deconvolution is used to ensure that the reference signal is nulled when data for the two halves are combined.¹² In the latter case, reference deconvolution is used as normal except that the ideal reference signal is phase-modulated as a function of t_1 , and the extraction of the experimental reference signal requires automatic phase and baseline adjustment of the reference region of the (t_1, F_2) spectra.¹³

4 APPLICATIONS

4.1 Lineshape Correction

One of the earliest applications of reference deconvolution, and still the most widespread, is for the correction of instrumental errors in lineshape. Figure 3 offers an extreme example, in which a 300 MHz proton spectrum of a sample of orthodichlorobenzene and tetramethylsilane (TMS) was acquired under conditions of sample spinning and poor shimming. The raw spectrum of Figure 3(a) shows severe lineshape asymmetry and spinning sidebands. Reference deconvolution with a target lineshape of a 0.2 Hz wide Lorentzian ($t_e = 5/\pi$ s, $t_g = \infty$ in equation 4) using a 50 Hz wide region of the spectrum containing the TMS signal yielded the corrected spectrum of Figure 3(b), while setting a target lineshape of a 0.2 Hz Gaussian ($t_e = \infty$, $t_g = 2.65$ s in equation 4) gave the spectrum of Figure 3(c). Note the ^{29}Si and ^{13}C satellites visible in the TMS region of Figures 3(b) and 3(c); if these are omitted from the ideal reference signal, spurious negative sidebands appear in the corrected spectrum.

Figure 3 is illustrative of the sort of improvement obtainable, at relatively modest cost in signal-to-noise ratio, even

Figure 3 Reference deconvolution of a 300 MHz proton spectrum of a solution of orthodichlorobenzene and TMS in deuterioacetone. (a) Raw spectrum; (b) after reference deconvolution with a target lineshape of a 0.2 Hz wide Lorentzian; and (c) after reference deconvolution with a target lineshape of a 0.2 Hz wide Gaussian. The horizontal arrow indicates the reference region used. (Adapted from Progress in Nuclear Magnetic Resonance Spectroscopy, Vol. 31, G. A. Morris, H. Barjat and T. J. Horne, Reference Deconvolution Methods, pp 197–257, Copyright (1997), with permission from Elsevier Science)

where there are severe lineshape distortions. In spectra where the natural widths of the lines of interest are significantly greater than that of the reference signal, as is generally the case, resolution enhancement is easily obtained by using a negative time constant t_e and a positive t_g in equation (4). This leads to over-enhancement of the reference line, generating negative side-lobes, but enhanced resolution for the remainder of the spectrum. The application of reference deconvolution is not restricted to spectra, such as that of Figure 3, which have relatively high signal-to-noise ratio. The basic requirement is that the signal-to-noise ratio of the reference signal be at least as good as that of the signals of interest, as otherwise the noise in the reference region would lead to visible noise being convoluted onto the remainder of the spectrum. Reference deconvolution is not uniformly successful; in the small minority of situations where there is significant multiplet character to the experimental lineshape, so that nodes appear in the time-domain signal, the width of target lineshape for which clean results are obtained is limited by the time at which the first zero appears in the experimental signal envelope.

Lineshape correction by reference deconvolution finds a wide variety of uses in NMR. It is particularly helpful in dynamic NMR, where instrumental contributions to the experimental lineshape interfere with attempts to extract dynamic information by bandshape fitting;¹⁴ in diffusion-ordered spectroscopy, where small magnetic field perturbations following the application of field gradient pulses can distort lineshapes and lead to overestimation of diffusion coefficients;¹⁵ and in

in vivo NMR,⁷ where accurate shimming is frequently impossible. It has also been used in single crystal solid state NMR, and for the suppression of unwanted sidebands from a variety of sources. Although not strictly an application of lineshape correction, examination of the correction function $c(t)$ for 1D spectra can be a valuable diagnostic tool in tracking down instrumental problems.

4.2 Difference Spectroscopy

One of the families of NMR techniques most susceptible to instrumental irreproducibility is that of difference spectroscopy. The most common example is the NOE (nuclear Overhauser effect) difference technique, in which a difference is typically taken between an unperturbed spectrum and one acquired following selective saturation of a particular proton signal. Because Overhauser effects are typically small for small molecules in mobile solution, this technique is normally carried out only on samples with strong signals. This has the result that almost all such spectra show substantial difference artifacts, typically in the form of spurious signals which appear to be in dispersion mode. In fact such artifacts usually arise from small frequency differences between the saturated and unperturbed spectra, and hence cannot be adjusted to pure absorption mode. Although frequency errors frequently dominate, small changes in lineshape (especially if there is some probe heating as a result of the saturating irradiation), pulse phase errors etc., also contribute. All of these ills can be treated by using reference deconvolution to ensure that the reference signal has

the same frequency, amplitude, phase and shape in both spectra. Provided that precautions are taken to avoid frequency-dependent perturbations of the spectra, the resultant difference spectra can be extremely clean.¹⁶

Figure 4(a) shows the normal spectrum of the species **1**, Figure 4(b) a hundred-fold vertical expansion of the corrected NOE difference spectrum following irradiation of proton 6, and Figure 4(c) the uncorrected difference spectrum. At such an expansion the uncorrected spectrum shows severe difference artifacts, but these are almost completely absent in the corrected spectrum. In the uncorrected spectrum only Overhauser effects greater than about 1% can be identified unequivocally, whereas the corrected spectrum shows a clean 0.5% NOE to the methyl signal at 0.9 ppm. The complete nulling of the signal of the trimethylsilyl blocking group, which is not expected to show any NOE, is particularly gratifying. This shows that the reference deconvolution process matches the signal amplitudes in the two parent spectra to better than 1 part in 10^4 , or in other words would allow the detection of NOE's as small as 0.01% for such a signal.

4.3 2D NMR

Considerable improvements in spectral quality can be obtained by the use of reference deconvolution to correct the t_1 -noise that results when instrument instability causes – as it inevitably does – different increments of a 2D NMR experiment to be acquired under slightly different conditions. If reference deconvolution is to correct in 2D NMR all of the errors that it can correct in 1D, it is necessary that all the signals of interest follow the same coherence transfer pathway, as otherwise any errors in pulse phase will have different effects on signals following different pathways. Of course, in experiments where other sources of t_1 -noise that do not affect the relative phases of pulses and signals are dominant, the requirement of a single pathway may be relaxed.

The simplest example of a single pathway 2D experiment is gradient-enhanced COSY,¹⁷ in which field gradient pulses

Figure 4 300 MHz proton spectra of compound **1**. (a) Normal spectrum; (b) NOE difference spectrum corrected by reference deconvolution using a 140 Hz wide reference region centered on the chloroform signal at 7.24 ppm, and expanded vertically $\times 100$; and (c) uncorrected difference spectrum, with the same expansion but truncated as indicated by the horizontal bars

Figure 5 500 MHz gradient COSY spectra of compound **2**. (a) Raw and (b) corrected COSY spectra, with (c) and (d) vertical expansions of the corresponding F_1 cross-sections through the residual proton signal from the solvent. (Adapted from T. J. Horne and G. A. Morris, *J. Magn. Reson. Ser. A*, 1996, **123**, 246, by permission of Academic Press)

either side of the mixing pulse are used to enforce either the coherence transfer echo or the antiecho pathway.

Figure 5 shows the results of a simple gradient COSY experiment on a solution of the tetracyclic orthoamide **2** in deuterioacetone with TMS as reference. To correct the experimental data, the raw free induction decays were treated with a mild Gaussian weighting to prevent truncation artifacts, zero-filled, and Fourier transformed with respect to t_2 . Each of the resultant spectra was then subjected to reference deconvolution using an 88 Hz wide region around the TMS signal, and the corrected free induction decay stored. Automatic zero-order phase and linear baseline correction were applied to the reference region, and a target lineshape of a 3 Hz wide Lorentzian, phase modulated as a function of t_1 at the TMS offset from resonance, was used. The 2D spectra of Figure 5(a) and (b) show the raw and corrected data respectively, following

sinebell multiplication, zero-filling and double Fourier transformation. The corresponding F_1 cross-sections Figure 5(c) and (d) through the residual solvent peak at 2.04 ppm show the reduction in t_1 -noise achieved by reference deconvolution. The signal-to- t_1 -noise ratio increases from 2600:1 to 110 000:1, a 40-fold improvement. Interestingly, the reduction in the noise level reveals some small signals attributable to dipolar demagnetization field effects, which are not normally seen in spectra of relatively dilute samples.

1 INTRODUCTION

In general, the effective magnetic field at a nucleus depends on the orientation of the molecule in the applied field. In the simplest case of a dilute spin- $\frac{1}{2}$ system, the orientation dependence is due to the anisotropy of the chemical shielding. Typically, the electron density in a molecule is highly anisotropic, with accumulations along the bond axes between neighboring nuclei. This leads to complicated electron currents which depend on the direction of the applied magnetic field relative to the bond axes. At experimentally accessible applied field strengths, where only the first-order effects on the electrons are observed, the chemical shielding is most generally expressed in linear algebraic terms as a second-rank tensor with elements $A\sigma_{ij}$ which specify the magnitude of the i th element of the induced magnetic field vector at nucleus A when the applied magnetic field is along direction j . In most cases, the asymmetry of the tensor is not measurable¹⁻³ and the effective chemical shielding tensor is the symmetric tensor equal to half of the sum of the exact tensor and its transpose. This symmetric tensor has a principal axis system in which it is diagonal and three principal values (conventionally $\sigma_{11} \leq \sigma_{22} \leq \sigma_{33}$) corresponding to the chemical shielding along the three principal axes. Detailed information about the electron distribution around the nucleus is thus summarized in six chemical shielding parameters (the six elements of the symmetric tensor, or the three principal values and the three Euler angles for the principal axis system). For this reason chemical shielding tensors have attracted considerable experimental and theoretical interest.^{4,5}

All six chemical shielding parameters can be measured if a single crystal of sufficient size is available which allows the molecules to be studied in at least six appropriately chosen orientations relative to the applied field.⁶ In powder samples, all molecular orientations are represented at the same time, with corresponding chemical shifts. The result is a broad signal with a characteristic shape known as a powder pattern [see, for example, Figure 1]. Although all orientational information has been lost, the three principal values of the shielding tensor, which specify the maximum, minimum, and most common

Figure 1 Proton decoupled ^{31}P spectra, at 119.05 MHz, of barium diethyl phosphate spinning at the magic angle²⁰

chemical shifts, are apparent in the discontinuities of the powder pattern.⁷ This is the most straightforward way to measure the three principal values of the shielding tensor. However, in many samples (notably biological ones) the discontinuities of the powder pattern may be obscured by overlap of multiple powder patterns and by poor signal-to-noise ratio due to the dispersal of the signal intensity over the breadth of the powder pattern. Two-dimensional (2D) correlation spectroscopy on reoriented samples can be used to sort overlapped powder patterns,⁸ but the signal-to-noise

ratio is further deteriorated by the dispersal of signal intensity over 2D powder patterns.

Motional averaging reduces the effective range of chemical shielding, thereby improving both resolution and signal-to-noise ratio. In the limit of rapid isotropic tumbling, all of the signal is found at the average of the principal values of the chemical shielding (i.e. one-third of the trace of the tensor which is invariant to rotation). This isotropically averaged signal is observed for molecules in solution unless they are so large that the rotational diffusion is too slow. When the natural motion is not sufficiently fast or isotropic, the isotropic average of the chemical shift (or any second-rank tensor, such as the dipolar interaction) can be produced mechanically by spinning sufficiently rapidly about an axis tilted at the ‘magic angle’, $\cos^{-1}(\frac{1}{3}) = 54^\circ 44'$, relative to the direction of the applied field.^{9,10}

While rapid magic angle spinning (MAS) provides high-resolution spectra of solid, dilute spin- $\frac{1}{2}$ systems, all information about the chemical shielding anisotropy (and hence the underlying anisotropy of the electron density) is lost. Use of rotor-synchronized rf pulses to prevent averaging in a second evolution period yields 2D spectra with powder patterns in the second dimension positioned at the isotropic chemical shift in the first dimension.¹¹ Similar results can be obtained by purely mechanical means, using ‘magic angle hopping’¹² or ‘stop-and-go spinning’.¹³ This use of a second dimension to separate powder patterns that overlap in one dimension allows direct determination of the principal values of the chemical shift. However, the experiments are relatively demanding and do not address the signal-to-noise problem of powder patterns.

Anisotropic information can also be recovered by MAS at rates that are too small to average the chemical shielding anisotropy completely.¹⁴ Spinning a crystallite at a frequency ω_r in the laboratory frame of reference, results in an applied field that swings around a cone with a frequency ω_r in the crystallite frame of reference [see equation (1) in Herzfeld and Berger¹⁵]. The chemical shielding of spins in the crystallite therefore oscillates around the isotropic value during the rotor period. The corresponding modulation of the Larmor precession produces a free induction decay for each crystallite with frequency components at integral multiples of ω_r above and below the isotropic value [see equation (21) in Herzfeld and Berger¹⁵]. The magnitudes and phases of these components will depend on the differences between the three principal values of the chemical shielding and on the initial orientation of the crystallite (given by three Euler angles). However, for a ‘carousel’¹⁶ of crystallites with orientations related by a uniform distribution of rotations around the rotor axis (corresponding to integration over the Euler angle γ in Herzfeld and Berger¹⁵), out-of-phase contributions cancel to produce a pure absorption NMR spectrum, consisting of a band at the isotropic frequency (the centerband) flanked by sidebands spaced at the spinning frequency with magnitudes depending on the values of the other two Euler angles and the differences between the principal values of the chemical shielding [see equation (24) in Herzfeld and Berger¹⁵]. It follows that the spectrum of a powder sample, representing contributions from the full range of the other two Euler angles, is also purely absorptive (see also Levitt,¹⁶ Maricq and Waugh,¹⁷ and Gullion and Conradi¹⁸) and that the magnitudes of the sidebands in the MAS powder spectrum will depend on the differences between the three principal values of the

chemical shielding. The span, $\Omega = \sigma_{33} - \sigma_{11}$, and the skew, $\kappa = (\sigma_{11} + \sigma_{33} - 2\sigma_{22})/(\sigma_{33} - \sigma_{11})$,¹⁹ can therefore be derived from the sideband intensities, while the isotropic average, $\sigma_{\text{iso}} = (\sigma_{11} + \sigma_{22} + \sigma_{33})/3$, is given by the position of the centerband. Analysis of slow MAS spectra thus presents an opportunity to determine experimentally all three principal values of the chemical shift without sacrificing resolution or signal-to-noise ratio.

Fortunately, the assignment of band order in slow MAS spectra is straightforward because the position of the centerband is independent of spinning speed and the associated sidebands are all spaced at the spinning frequency. Unfortunately, however, the dependence of the sideband intensities on the principal values of the chemical shielding is complicated, as illustrated by the example in Figure 1. Two approaches have been taken to extract the span and skew from the sideband intensities. Maricq and Waugh²¹ have made use of the relatively simple dependence of the second and third moments of the sideband pattern on the span and skew. On the other hand, Herzfeld and Berger¹⁵ have focused on the practical benefits of working with the ratios of the sideband intensities. We review both of these methods.

2 MOMENTS

Using I_N to represent the intensity of the N th sideband (the signal at the frequency $N\omega_r$ above the isotropic frequency), the k th moment of a slow MAS spectrum is given by

$$M_k = \omega_r^k \sum_N N^k I_N / \sum_N I_N \quad (1)$$

Maricq and Waugh²¹ found that the span and skew can be derived from the second and third moments according to the equations

$$\Omega = (1/2)\delta(3 - \eta) \quad (2)$$

and

$$\kappa = (3/2)\delta(1 + \eta)/\Omega \quad (3)$$

where δ is given by

$$8\delta^3 - 30M_2\delta - 35M_3 = 0 \quad (4)$$

and η is given by

$$\eta^2 = [15(M_2/\delta^2) - 3] = [1 - (35/2)(M_3/\delta^3)] \quad (5)$$

Equations (4) and (5) have three solutions for δ , each with two solutions for η . These six solutions correspond to the six permutations of the three principal values of the chemical shielding.

The accuracy of this method of sideband analysis clearly depends critically on the accuracy of the determination of the two moments. In practice, this requires that all the sidebands be resolved from other contributions to the spectrum. In addition, the sensitivity of the moments to the intensities of the higher order sidebands necessitates accurate measurement

4 SIDEBAND ANALYSIS IN MAGIC ANGLE SPINNING NMR OF SOLIDS

Figure 2 Contour plots of I_N/I_0 for values of N as indicated in (a)–(e).¹⁵ This half strip corresponds to the convention $\sigma_{11} \leq \sigma_{22} \leq \sigma_{33}$. The five other permutations of the principal values correspond to the half strip for $\mu < 0$ and the four quadrants above and below the half strips

of weak signals that may be obscured by noise. The effects of inaccuracies in the measurement of higher order sidebands have been considered by Clayden et al.²² in applications to slow MAS ^{31}P spectra of sodium dihydrogen orthophosphate, with a nonaxial shielding tensor, and triphenylphosphine oxide, with an axial shielding tensor. It was found that omitting sidebands of only 1% of the intensity of the most intense sideband was enough to produce significant variability in the derived principal values of the shielding. M_3 is the more vulnerable to inaccuracy than M_2 and examination of equations (4) and (5) shows that if $|M_3| > (\frac{2}{35})(5M_2)^{\frac{3}{2}}$ there is only one real solution for δ and no real values for η . This is a particular problem in the case of near axial tensors, for which $|M_3|$ is especially large compared with M_2 and η^2 tends toward zero. Inaccuracies in this regime easily lead to imaginary values of η . (See for example the case of triphenylphosphine oxide in Herzfeld et al.²⁰) In general, moment analysis demands superb signal-to-noise ratio, especially for near axial tensors.

3 SIDE BAND RATIOS

Reliance on high-order sidebands, or any particularly inconvenient sidebands, can be avoided by using a search procedure to find those values of the span and skew that provide the best match to the intensities of the relatively

accessible sidebands alone. In this process it is necessary to use ratios of sideband intensities for normalization.¹⁵ Usually the centerband is one of the relatively strong sidebands and so it is convenient to use that for normalization. This places a special burden on accurate measurement of the intensity of the centerband and if this is not convenient other ratios can be used instead (see, for example, Fenzke et al.²³). In the search for the best fit of the available intensity ratios, it is computationally demanding to calculate sideband intensities directly for every change in span and skew [e.g., using equations (24) and (33) Herzfeld and Berger,¹⁵ for example]. Excellent accuracy can be obtained with much improved speed by bicubic spline interpolation between values calculated on a grid of points in the parameter space.¹⁵ Such a grid of values is available for the intensities of the $N = 0, \pm 1, \pm 2, \pm 3, \pm 4, \pm 5$ bands, for values of the scaled span $\mu = (\gamma B/\omega_r) \Omega$ (where γ is the gyromagnetic ratio of the nucleus and B is the strength of the applied field) from 0 to 15,¹⁵ and can be extended to larger spans²⁴ and higher orders,²³ as necessary.

In order to make good use of sideband intensity ratios, it is helpful to examine their dependence on the span and the skew graphically. Figure 2 shows contour plots for the intensity ratios $I_{\pm N}/I_0$, for $N = 1$ to 5. These graphs have several uses. First, they can be used to estimate graphically the span and skew for a particular set of experimental intensity ratios by locating the intersections of the corresponding contours. An example is shown in Figure 3 for barium diethyl phosphate. The graphical estimate of span and skew may suffice for some

Figure 3 Graphical analysis of sideband intensity ratios I_N/I_0 from a ^{31}P spectrum, at 119.05 MHz, of barium diethyl phosphate spinning at 1.705 kHz.¹⁵ Notice that the contours for $N > 0$ appear as they do in Figure 2, while the contours for $N < 0$ appear flipped over. This is necessary to superimpose corresponding values of κ . The estimated values of the scaled span, μ , and the skew, κ , are indicated with two different estimates of uncertainty by the circle and rectangle at $\mu \approx 13$ and $\kappa \approx 0.4$

purposes (see, for example, graphical ^{31}P results for sodium dihydrogen orthophosphate and triphenylphosphine oxide in Tables 1 and 3 of Clayden et al.²²) or may be used as the starting point of a numerical fitting procedure for greater refinement.

The graphs in Figure 2 can also be used to design experiments. For example, it is clear that the intensity ratios are insensitive to the skew (as indicated by nearly vertical contours) for small values of μ . Thus a sufficiently low spinning speed must be chosen for μ to be large enough to obtain information about the skew. For near axial tensors (κ tending toward ± 1), the graphs show that μ must be even larger to obtain spectra sensitive to the skew. This difficulty has been noted by Clayden et al. for the nearly axially symmetric ^{31}P tensor of triphenylphosphine oxide, as compared with the nonaxial ^{31}P tensor of sodium dihydrogen orthophosphate (see Figures 3 and 8 of Clayden et al.²²). Nevertheless, in both cases, graphical analysis of sideband ratios gives reasonably good estimates for the principal values of the chemical shielding, in contrast to the results of moment analysis (see Tables 1 and 3 of Clayden et al.²²). For small

spans, the spinning speed may need to be impractically low to obtain informative values of μ . However, for such narrow tensors, the skew is not of great practical interest because the three principal values are so similar.

4 SIMULATIONS

The reliability of the above methods depends on the extraction of accurate intensities for individual bands in slow MAS spectra. If the centerbands are well resolved, then overlap of sidebands with centerbands can be avoided by careful choices of spinning speeds or, for busier spectra, by a 2D experiment that sorts sidebands according to their isotropic chemical shifts.^{25,26} However for spectra with overlapping centerbands or poor signal-to-noise ratio, extraction of accurate band intensities is not possible. In these cases, a more suitable approach is a direct least-squares fit of the full spectrum.²² A relatively rapid scheme for such a fit was developed by deGroot et al.²⁷ Spectra are simulated for trial parameters by convolving a simple lineshape with sideband

Figure 4 Carbon-13 MAS difference spectra and simulations for 14-¹³C-retinal-labeled bacteriorhodopsin at (a) neutral pH with spinning speed 2.0 kHz²⁷ and (b) at low pH with spinning speed 3.0 kHz.²⁸ Chemical shifts are relative to TMS. The centerband is marked for each species by an asterisk or a letter. The least-squares simulations are represented by smooth lines. For the overlapped signals at low pH, the components that constitute the fit are also shown. Below each spectrum the residues are shown

intensities calculated by interpolation between stored values on a grid of points in span-skew space (from Herzfeld and Berger¹⁵). These calculated bands are positioned on a polynomial background according to the isotropic shifts and spinning speed. Least-squares iteration of the parameter search is pursued until the residuals reach the noise level. Figure 4 shows the results of such fits for a sample of 14-¹³C-retinal-labeled bacteriorhodopsin at neutral pH and at low pH. At neutral pH, there are two species and their signals are fully resolved. In this case, the virtue of the fit is in the objective treatment of the noise. At low pH, four species are present, with some overlap of centerbands. In this case, the fit is essential for treating overlap, as well as noise.

5 COMPLICATIONS

Errors in sideband analysis may arise from noise in the spectrum or from mistaken theoretical assumptions. For analyses using moments or sideband ratios, the most straightforward means of assessing noise-limited accuracy is to repeat the analysis for variations of the measured sideband intensities over the range of values consistent with the noise.²⁹ This is preferable to arbitrary cut-offs in the acceptable

overall deviations between theory and experiment.^{23,29} For simulations, more rigorous sensitivity analysis is possible. In this case, it is convenient to choose a nonlinear least-squares fitting package that includes built-in statistical error estimation.²⁷

The fundamental theoretical assumption made in the usual sideband analysis is that the chemical shielding is the only source of anisotropy. This is appropriate for a dilute spin- $\frac{1}{2}$ system with proton decoupling. However, cross polarization is an important tool in solid state NMR. In MAS experiments with cross polarization, Jeschke and Grossmann³⁰ reported systematic deviations between simulated and the experimental sidebands. They point out that the normal assumption that the magnetization of spins is independent of molecular orientation may be invalid for cross-polarized spins due to: (i) Hartmann-Hahn mismatch anisotropy, (ii) for short contact times, anisotropic orientation of the heteronuclear pair axis, and (iii) for long contact times, anisotropic relaxation in the rotating frame.

Other sources of anisotropy are also of interest. Spin- $\frac{1}{2}$ systems with heteronuclear dipolar interactions still behave inhomogeneously and various strategies of sideband analysis can be used to determine the strength of the dipolar interaction and the orientation of the heteronuclear axis relative to the principal axes of the chemical shielding.^{21,31,32} Sideband analysis is also useful for systems with weak quadrupolar interactions.^{21,33} However, systems with homonuclear dipolar interactions or strong quadrupolar interactions do not behave inhomogeneously and do not lend themselves to sideband analysis.^{21,34,35}

1 INTRODUCTION

Spectral editing techniques in NMR in general are methods that aid the spectroscopist in assigning or simplifying complex high-resolution spectra. Most approaches to spectral editing have been developed in the context of NMR of ^{13}C where the emphasis has been on separating ^{13}C resonances on the basis of their multiplicity, i.e. the number of directly attached ^1H s. This type of information, when combined with the analysis of ^{13}C chemical shifts, is very often sufficient for determining the chemical structure of rather complex organic molecules. As such, spectral editing of solution NMR finds wide application in industry for the structural characterization of polymers, drugs, and petroleum based products. Development of similar methods which are applicable to solid samples has been motivated by a large number of important applications to geochemical and material science.

This article deals with spectral editing approaches developed specifically for high-resolution solid state NMR of ^{13}C . Many different strategies have been applied to this problem, and the space provided here unfortunately does not permit covering every aspect of this subfield. Most of the relevant literature is cited in two recent papers,^{1,2} and the interested reader may find more extensive citations contained therein.

2 BACKGROUND ON SPECTRAL EDITING OF LIQUIDS

The high information content of ^{13}C NMR spectra of liquids is well known. It follows directly from the large dispersion of the ^{13}C chemical shift and the remarkably tight correlation of ^{13}C chemical shifts with structure. The beautiful stick-spectrum simplicity of ^{13}C spectra is made possible by ^1H decoupling and the low natural abundance of ^{13}C which eliminates complications from ^{13}C – ^{13}C J couplings. Their information content is greatly increased if the multiplicity of the ^{13}C resonances can be determined.

Editing techniques for ^{13}C NMR of liquids rely on the fairly narrow range of values for $^1J(^{13}\text{C},^1\text{H})$. This permits one to devise pulse sequences in which the evolution of the ^{13}C magnetization can be made to depend principally upon the number n of directly attached ^1H s in CH_n groups. The attached proton test (APT) is the simplest example. In its most basic form, a $\pi/2$, τ , π , τ , acquire echo sequence is applied to the ^{13}C with ^1H decoupling during acquisition. A π pulse is also applied to the ^1H s after the first τ , resulting in J modulation of the ^{13}C spin echo. During the 2τ evolution period the dephasings of the ^{13}C chemical shifts are refocused, while those due to $^1J(^{13}\text{C},^1\text{H})$ accumulate. Setting τ to $\frac{1}{2}J$ produces a spectrum in which the CH_3 and CH_1 resonances are inverted, while the CH_2 and CH_0 resonances are absorptive.

For complex ^{13}C spectra, more powerful methods are required, but all rely upon J couplings in some manner. In editing protocols based on INEPT, J modulation is used to label the ^1H magnetization which is then transferred to the ^{13}C (see *INEPT*). The various CH_n groups can be amplitude modulated in distinct ways depending upon the length of the time evolution due to J coupling. On this basis schemes can be devised in which linear combinations of a few different experiments produce CH_3 -only, CH_2 -only, CH_1 -only, and CH_0 -only spectra. Techniques utilizing DEPT provide some improvement in selectivity, as the differentiation of CH_n groups depends upon a pulse flip angle rather than a period τ of free evolution under $^1J(^{13}\text{C},^1\text{H})$. Especially clean separation of CH_n subspectra has been achieved using multiple quantum coherence among the J -coupled spins. This subspectral editing using a multiple-quantum trap (SEMUT) has the advantage of being relatively insensitive to the value of $^1J(^{13}\text{C},^1\text{H})$.

3 CHALLENGES POSED BY SOLIDS

As discussed elsewhere in the Encyclopedia, obtaining high-resolution ^{13}C spectra of organic solids requires both magic angle spinning (MAS) and high-power decoupling of the protons. These techniques are usually combined with cross polarization (CP) in a CP MAS experiment. The need to remove broadening associated with chemical shift anisotropy and ^{13}C – ^1H dipolar couplings presents a new set of problems in the design of methods for spectral editing. Over the last 20 years of development in high-resolution NMR of solids three basic strategies have been applied to this problem. The first has been to design pulse sequences which produce J -modulated signals in solids, and thereby directly adapt the techniques just discussed to solids. The others use ^{13}C – ^1H dipolar couplings as the basis for selection of CH_n . Some of these methods use the relative strengths of dipolar couplings or rates of CP to differentiate ^{13}C signals of different multiplicities. Others rely upon the establishment of quasi-equilibrium states in the CP process and thus differentiate the ^{13}C multiplicities on the basis of the ratio of the inverse rotating frame spin temperature of the ^{13}C to that for its directly bonded protons.

3.1 J Modulation in Solids

Observing resolved $^1J(^{13}\text{C},^1\text{H})$ -coupled multiplets in CP MAS ^{13}C spectra of solids is made difficult by the strong

^1H – ^1H and ^1H – ^{13}C dipolar couplings. In the absence of strong on-resonance ^1H decoupling, CP MAS spectra of typical rigid samples are broad and relatively featureless. The ^1H – ^{13}C dipolar broadening is by itself inhomogeneous, and should therefore be suppressed by MAS. However the spin-exchange mediated by the ^1H – ^1H dipolar couplings is faster than typical rates of MAS. Therefore the spin states of ^1H can change several times during a MAS cycle, and the average of the ^1H – ^{13}C dipolar interaction is then no longer zero. In a simplified picture one can consider this to be a lifetime broadening of the ^{13}C resonances due to the short lifetime of the spin states of the directly attached protons. Terao and co-workers³ first demonstrated that suppression of the ^1H – ^1H dipolar couplings could make it possible to observe $^1J(^{13}\text{C},^1\text{H})$ -coupled multiplets in solids. In their work, ^1H decoupling at the magic angle in the rotating frame was first used. Subsequently a number of homonuclear sequences such as MREV-8 have been applied as homonuclear multiple pulse decoupling (MPD) for this purpose. For systems such as plastic crystals where molecular motion has already appreciably averaged the dipolar couplings, MPD produces CP MAS spectra with well-resolved $^1J(^{13}\text{C},^1\text{H})$ coupled multiplets. The couplings observed are reduced by the scaling factor appropriate to the particular MPD sequence used.

This approach has been extended to editing schemes that most resemble those used in liquids. The basic approach is to insert MPD sequences in the periods of free evolution under $^1J(^{13}\text{C},^1\text{H})$. APT-type spectra of motionally narrowed solids have been acquired in this fashion, but in the general case the MPD does not produce sufficient narrowing of the proton NMR spectra to permit sustained J modulation. Terao and co-workers⁴ have investigated the limitations of this approach most extensively for rigid solids. One sequence they have successfully used in producing J modulation for rigid solids consists of CP followed by a J -modulated rotor synchronized echo. During the first half of the echo, magnetization of the ^{13}C nuclei evolves under proton homonuclear decoupling. This period, t_1 , is adjusted to be equal to one rotor cycle. Over the course of the rotor period J modulation accumulates, but any modulation by the ^{13}C – ^1H dipolar coupling and the ^{13}C CSA is refocused. After the π pulse, high-power dipolar decoupling is applied for another period t_1 . This second interval refocuses the isotropic chemical shift and effects of any bulk susceptibility broadening that accumulated during the first t_1 period. FIDs taken as a function of t_1 then are largely only modulated by $^1J(^{13}\text{C},^1\text{H})$. In this manner a 2D heteronuclear J -resolved spectrum can be obtained with multiplets in the ω_1 dimension. However this approach still does not yield clean multiplets. For instance, the outer lines in quartets for CH_3 groups are very much broader than the central pair, and they are barely resolved.

At the moment, J modulation based editing techniques for solids will remain useful only for systems with significant motional narrowing. Advances in the efficiency of homonuclear decoupling, especially under conditions of MAS, are needed before such techniques can become widely applicable. Problems also remain in combining these homonuclear decoupling requirements with the typical hardware used for CP MAS NMR. While the approach has been proven in principle, development of generally applicable methods for solids along these lines remains a challenge for the future.

3.2 Dipolar Dephasing and Related Schemes

The most generally applicable editing techniques for solids take advantage of the strong dipolar couplings inherent in solids, rather than treating them as a nuisance to be eliminated. The simplest approach to spectral editing in CP MAS NMR of organic solids is the venerable technique⁵ of dipolar dephasing (DD) or interrupted decoupling. After CP, the ^1H decoupler is turned off for $\sim 50\ \mu\text{s}$. This is a sufficient time for the ^{13}C – ^1H dipolar coupling to dephase the transverse magnetization for any ^{13}C with a directly bonded ^1H , as long as the dipolar coupling is not motionally averaged. Therefore the lines for rigid CH_1 and CH_2 groups are effectively suppressed. Rapid rotation of CH_3 groups at room temperature leads to different behavior for these protonated carbons. This rotation renders the three ^{13}C – ^1H dipolar couplings equal, and reduces them to one-third of their static value. Depending upon the spin state of the protons, the ^{13}C in a CH_3 group can experience one of two possible dipolar fields. Whenever the three protons are in the same state ($\alpha\alpha\alpha$ or $\beta\beta\beta$), the three couplings reinforce one another, and the ^{13}C experiences the field of a single full ^{13}C – ^1H dipolar coupling. However, three-quarters of the time the ^1H s are in a state such as $\alpha\alpha\beta$ or $\beta\beta\alpha$. In this instance the fields due to two of the couplings will exactly cancel. The net dipolar field then is usually only one-third of a single ^{13}C – ^1H dipolar coupling, and this is similar to that often experienced through nonbonded contacts by a CH_0 . Thus, in most instances, methyl groups at room temperature behave like nonprotonated carbons under dipolar dephasing. The DD spectrum then consists of slightly attenuated resonances for just the CH_0 and CH_3 groups. Comparison with a fully polarized CP MAS spectrum provides a simple qualitative method for categorizing resonances as either $\text{CH}_3 + \text{CH}_0$ or $\text{CH}_2 + \text{CH}_1$. In many instances, a simple CP MAS spectrum can be fully assigned using this approach in combination with information from linewidth or chemical shifts.

Several approaches have been taken to improve on the basic DD technique. In some instances the dephasing interval leads to an unacceptable linear phase correction due to the delayed acquisition. A π pulse may be inserted in the interrupted decoupling interval to alleviate this to some degree. However, as first pointed out by Munowitz and Griffin,⁶ the π pulse should be applied only after a full rotor period to ensure that both the isotropic and anisotropic portions of the ^{13}C chemical shift are refocused. Other groups have investigated the spin dynamics of the DD experiment with the desire to separate CH_n resonances more completely or quantitatively.⁷ The approach has been to fit the dephasing of the ^{13}C resonances as a function of the dephasing time, τ_D , to some type of model dephasing function. Since it can be argued the different CH_n groups may have characteristic dephasing characteristics, this approach would seem to have some validity. In this manner one can then extrapolate back in dephasing time to recover the initial intensities of the CH_3 and CH_0 resonances.

The best way to view the DD experiment is actually as a low-resolution 1D version of separated local field (SLF) spectroscopy under MAS conditions. During τ_D the ^{13}C FID is dominated by the ^{13}C – ^1H dipolar couplings, and is damped by the ^1H – ^1H dipolar interactions. An isolated CH_1 group then has a decay profile that is essentially a damped Pake doublet FID, that for a CH_2 , i.e. a Pake ‘triplet’. Since the local structure of isolated CH_n groups of a given n does not

vary appreciably in organic solids, these decays would be quite characteristic were it not for the ^1H – ^1H dipolar couplings. This complication can be removed by applying MPD during the dephasing interval. In this manner the number of dipolar couplings is determined from a spectral pattern, i.e. sideband intensities, rather than from a less structure-specific average dephasing rate.

The first proposal for this type of MAS SLF spectroscopy was by Munowitz and Griffin⁶ as a means of measuring C–H distances. Webb and the author⁸ later investigated using the spinning sideband patterns characteristic of the different CH_n groups for spectral editing. The proposed 2D experiment consists of CP followed by MPD (usually MREV-8) for t_1 to produce dipolar evolution in the first frequency dimension. This is followed by a $\pi/2(\phi_i)$, τ , $\pi/2(x)$ sequence to selectively project the ^{13}C magnetization onto one axis of the rotating frame. The period, τ , is a few hundred μs and is used to dephase magnetization not placed along z by the $\pi/2(\phi_i)$ pulse. Following the $\pi/2(x)$ pulse, the normal dipolar decoupled ^{13}C FID is acquired during time period t_2 . Cycling the phase ϕ_i in a time proportional phase incrementation scheme avoids the need to acquire a quadrature data set in t_1 . The sideband patterns generated this way in the ω_1 dimension retain both dipolar and CSA effects. However, at low-to-moderate field strengths the patterns are so dominated by the ^{13}C – ^1H dipolar couplings that they can still be easily deconvolved into their CH_n components. Since CH_2 groups have two dipolar couplings, they have nearly twice as many sidebands, and are readily distinguished from CH_1 groups by this technique. Decomposition of complex CP MAS spectra with many overlapping lines has been demonstrated using this approach. At higher fields the same deconvolution methods can be applied using Munowitz and Griffin's rotor-synchronized sequence to eliminate the complications due to CSA. The requirement for delaying acquisition to several rotor periods after the initial CP interval, however, can result in substantial losses in sensitivity. A further simplification has been proposed by Sethi.⁹ Since the temporal evolution during t_1 in the MAS SLF experiments is well understood, only a few special times t_1 need be acquired. Using this approach Sethi has introduced 1D editing schemes that also can be used to separate CH_1 and CH_2 resonances.

3.3 Schemes Using CP Dynamics

The previous methods rely upon the relative strengths of ^{13}C – ^1H dipolar couplings or the different numbers of dipolar couplings to discriminate between different CH_n groups. The dipolar couplings are used essentially to dephase or modulate the ^{13}C resonances in a predictable manner. Another strategy is to use the ways in which these differences in the dipolar coupling network result in differences in the CP dynamics between the CH_n groups.

The simplest description of the CP process considers the transfer as a first-order kinetic process with a time constant T_{CH} . However, it is well known that this description is only qualitatively correct, and only phenomenologically describes the long-time behavior ($t \gg T_2$). At short CP times the Hartmann–Hahn transfer is dominated by the details of the dipolar coupling network between a ^{13}C and its directly bonded ^1H s. In single crystals, one even observes transient

oscillations in the polarization transfer. For powdered samples under moderate MAS, the transient effect manifests itself as a rapid initial period of CP transfer in which the ^{13}C and its attached ^1H s come into a quasi-equilibrium. Spin diffusion to the more distant protons transports polarization more slowly to these ^1H s coupled to the ^{13}C . This slower process determines the rate at which the ^{13}C reaches its final fully polarized state. In the quasi-equilibrium state, the initially unpolarized ^{13}C nuclei share the polarization equally with their directly attached protons. CH_1 and CH_2 groups then polarize to one-half and two-thirds of their full intensity, respectively, on the short timescale. Because of their motionally averaged dipolar field, CH_3 groups behave similarly to nonprotonated carbons. Both the CH_0 and CH_3 groups then polarize more slowly, with the polarization bottleneck to full enhancement usually being the rate of ^1H – ^1H spin diffusion. As long as the transfer of transient polarization among the closely coupled spins is faster than the ^1H – ^1H spin diffusion and direct transfer from more distant protons, it can be put to good use in spectral editing schemes.

One particularly useful approach for distinguishing the signals of $\text{CH}_1 + \text{CH}_2$ from those of $\text{CH}_0 + \text{CH}_3$ based on the previous ideas is the depolarization (DEP) technique.¹⁰ After a several ms CP interval, the spin locked ^1H magnetization is allowed to dephase by turning off the ^1H rf for several hundred μs , while keeping the ^{13}C spin locked. Turning the ^1H rf back on reestablishes the CP contact, and the ^{13}C magnetization can be used to repolarize the depolarized ^1H s. If the phase of the ^1H rf is switched 90° every 25–50 μs over a total period of a few hundred μs , there will be no net buildup in the ^1H magnetization, only a net drain from the ^{13}C . Since only the $\text{CH}_1 + \text{CH}_2$ carbons polarize on this timescale, their signals are fully depleted after the depolarization, while the $\text{CH}_0 + \text{CH}_3$ signals are attenuated only slightly. The resulting DEP spectrum is much like a DD spectrum. However since the ^{13}C are spin locked until the depolarization is finished, there are no problems with linear phase errors as in DD.

Polarization inversion (PI) can also be used in a similar fashion.¹¹ In this technique the ^{13}C are first fully polarized by CP, and the phase of the rf in the ^1H channel suddenly inverted. Since the ^1H spin temperature has now been inverted, the ^{13}C will try to follow. Those ^{13}C with strong ^{13}C – ^1H dipolar couplings first quickly depolarize, and then repolarize in the opposite direction. Since the zero crossings for CH_1 and CH_2 groups are different, they can be used in some instances to distinguish resonances. Nulling of resonances in this manner has also been referred to as cross depolarization¹² (CPD). A further variant adds a final short polarization period onto the CPD sequence.¹³ The depolarization and repolarization periods in this cross-depolarization–repolarization technique (CPDR) can be adjusted so as simultaneously to null the CH_1 and CH_2 groups. This is not in general possible with the cross-depolarization interval alone.

Sangill et al.² have presented a thorough study of the use of CPD and CPDR in spectral editing. Their analysis focused on using optimized combinations of CPD and CPDR spectra to produce CH_n -only spectra, $n = 0$ –3, while maintaining good sensitivity. By paying careful attention to the CP dynamics, they were able successfully to separate complex CP MAS spectra into their CH_n subspectral components.

Burum and Bielecki¹⁴ have introduced a particularly clever method based on CP dynamics for selectively detecting CH_2

groups in CP MAS NMR. Their method, WIMSE (windowless isotropic mixing for spectral editing), starts with a CP interval under a multiple pulse cycle which eliminates the ^1H – ^1H dipolar couplings during the CP step while maintaining the ^{13}C – ^1H couplings. Over a MAS rotor period under these conditions, no net polarization is transferred to ^{13}C nuclei in CH groups. Instead, whatever magnetization is transferred at the start of the rotor cycle ‘echoes’ back from the ^{13}C to the ^1H at the end. However, the presence of two dipolar couplings in a CH_2 group defeats this ‘rotational polarization echo’ effect. The resulting spectrum then consists solely of the CH_2 component in a complex CP MAS spectrum. CH_3 and CH_0 lines do not appear as their CP rates are too slow.

3.4 Techniques Using Quasi-Equilibrium States

Another successful method based on differences in CP dynamics between the different CH_n groups is the solid state attached proton test, or SSAPT method. Initially the ^{13}C are fully polarized using a 2–3 ms CP interval. Immediately following this, a short PI period is applied, typically on the order of $50\ \mu\text{s}$. At the beginning of the PI time the ^{13}C and their directly attached ^1H s are equally polarized. Upon reversal of the phase in the ^1H spin locking rf, this equilibrium is broken, and the spins try to reequilibrate. Since the CH_3 and CH_0 groups polarize slowly, they are relatively unaffected by this short PI interval. The CH_2 and CH_1 groups, on the other hand, have sufficient time to reach a quasi-equilibrium state through a rapid transient CP transfer. In the case of the CH_1 group, the ^{13}C and the ^1H have equal but opposite polarizations at the start of the PI. During the short PI time these magnetizations cancel, and the signal for the CH_1 carbons is very effectively nulled. The ^{13}C nuclei in the CH_2 groups carry 1 unit of polarization as opposed to the -2 units in the ^1H s at the beginning of the PI interval. This results in -1 unit of total polarization to be shared among the three spins in the quasi-equilibrium state. At the end of the PI period, the CH_2 signal is then inverted with an intensity of $-\frac{1}{3}$ of its fully polarized signal. The SSAPT spectrum then has $\text{CH}_3 + \text{CH}_0$ signals nearly fully polarized and positive, CH signals nulled, and CH_2 signals inverted at one-third intensity. In many instances this provides a very straightforward means of separating the contributions from the different CH_n groups to a ^{13}C CP MAS spectrum.^{15,16}

This approach has been extended to a complete spectral editing protocol by Wu, Burns, and the author.¹ Since the establishment of the quasi-equilibrium state depends upon the ratio of the inverse rotating frame spin temperatures of the ^{13}C and its directly bonded ^1H s, this technique is less sensitive to the CP rates. In this sense it is a relatively robust editing procedure.

The complete spectral editing procedure due to Wu et al. uses four basic experiments (see Figure 1). One begins by acquiring a CH_2 -only spectrum. The sequence used starts with a short CP contact which polarizes the CH and CH_2 groups to their quasi-equilibrium intensities of $\frac{1}{2}$ and $\frac{2}{3}$ respectively. This is followed by a short PI interval of roughly the same length. During PI the CH signals null, as does any small CH_3 or CH_0 polarization built up during the CP step. The CH_2 ^{13}C magnetization goes to $-\frac{1}{3}$ of its initial value, resulting in a spectrum with $-\frac{2}{9}$ the intensity for these carbons. This

Figure 1 Sequences used in the editing protocol of Wu et al. All employ simultaneous phase inversion to alleviate problems with Hartmann–Hahn mismatches. (a) CP sequence. The additional spin locking delay τ_{SL}^S is used to make the total ^{13}C spin locking time the same in all of the sequences. (b) SCPPI sequence used to acquire CH_2 -only spectra. (c) Depolarization sequence. The time τ_{SL}^I is added in these sequences mainly to minimize distortions from ^1H rotating frame relaxation

short CP polarization inversion (SCPPI) spectrum then has contributions from only the CH_2 groups.

The second experiment is a short contact CP (SCP). This will have intensity principally from the CH and CH_2 carbons. Another short CP spectrum with a depolarization interval is also acquired (SCPD). The SCPD spectrum can be used to subtract out the contamination of the SCP data from CH_3 and CH_0 groups. Unfortunately the CH_3 and CH_0 carbons have sufficiently different CP dynamics that they are differentially attenuated, and this subtraction alone is insufficient. In most instances, however, the shift ranges for CH_3 and CH_0 groups are adequately separated so that a dividing line on the ^{13}C chemical shift scale can be chosen to separate these groups. Different weighting factors can then be applied to the upfield (CH_3) and downfield (CH_0) regions for this purpose. The result of this procedure is a relatively clean CH-only spectrum.

To acquire semiquantitatively correct CH_0 and CH_3 spectra, a long CP depolarization spectrum is acquired (LCPD). This spectrum is again split into CH_0 and CH_3 regions, and each part corrected for the differential signal loss of the two types of groups in the depolarization step.

The cleanest and most quantitative results are obtained with this method if the intensity factors for spectral decomposition are determined experimentally on a known model system.

Table 1 Typical Intensities for CH_n Resonances in Pulse Sequences Used for Spectral Editing

Experiment	CH_n			
	CH_0	CH_1	CH_2	CH_3
LCP	100	100	100	100
SCP	10.5	57.5	68	22.6
SCPPI	0	0	-22	0
SCPD	7.2	0	0	10.4
LCPD	82.5	0	0	57.5

Using the set of sequences shown in Figure 1, the intensity matrix in Table 1 is found to be typical. LCP is used to denote a standard (long) CP experiment which is used as the 100% intensity reference.

As the entries demonstrate, the CH and CH_2 group intensities in the SCPPI and SCP experiments are quite close to those expected from the quasi-equilibrium description of the CP dynamics.

Figure 2 compares the four spectra acquired in the editing protocol for cholesteryl acetate to the normal CP MAS spectrum. In the solid state there are two molecules in the unit cell producing a doubling of the lines. Furthermore, changes in conformation lead to significant shifts in many resonances. Using the intensity matrix in Table 1, the CH_n , $n = 0-3$, only spectra can be reconstructed from these data. The results of this data manipulation are shown in Figure 3, clearly demonstrating the simplifications made possible by this spectral editing approach. As a check on this editing protocol, one may sum the CH_n subspectra to produce a synthetic CP MAS spectrum. This is compared with the normal CP MAS

**Figure 3** Subspectra constructed from the data in Figure 2. (a) Normal CP MAS spectrum again for comparison. (b) CH_0 -only. (c) CH_1 -only. (d) CH_2 -only. (e) CH_3 -only. Some of the assignments made possible by the editing technique are given in the inset**Figure 2** Data from a spectral editing experiment on cholesteryl acetate. (a) Normal CP spectrum for comparison. (b) SCP spectrum. (c) SCPPI spectrum. (d) SCPD spectrum. (e) LCPD spectrum. In practice larger numbers of scans are acquired for the lower signal-to-noise experiments as indicated in the figure

spectrum in Figure 4, along with the difference of the two. The small differences observed indicate the reliability of the approach used.

4 EXPERIMENTAL CONSIDERATIONS AND CAVEATS

Except for the simplest approaches to spectral editing in solids, one must pay some extra attention to the experimental setup. In particular, very high MAS spin rates and rf inhomogeneity can adversely affect the CP dynamics relied upon in most methods. The sharpening of the Hartmann-Hahn condition, and the need to match typically on a sideband condition, $\omega_1 = \omega_2 + \omega_r$, makes a homogeneous rf field more important than in a standard CP MAS experiment. Good experimental practice requires stable rf levels, restricting the sample to well within the rf coil, and a stable spin rate. For experiments utilizing short CP, PI, or depolarization periods, additional modifications that make the matching condition less sensitive are needed. Our group has found the simultaneous phase inversion method^{1,14,15} easy to incorporate in editing schemes. The pulse sequences in Figure 1 utilize this approach to make the results much less sensitive to how well the matching condition is set and maintained throughout the experiment.

Figure 4 Comparison of the (a) normal CP MAS spectrum and (b) the synthetic one produced by direct summation of the subspectra in Figure 3(b)–(e). (c) The difference between the normal and synthetic CP MAS spectra

When spectra are to be combined in an editing procedure, it is also important to consider rf heating, droop in the rf levels, and $T_{1\rho}$ relaxation. Whenever possible, it is a good practice then to keep the rf fields on for comparable periods of time in the different experiments to be combined. The sequences in Figure 1 have been constructed to take these additional complications into account. Table 2 gives the set of delays in reference to Figure 1 that have been found to give optimal performance in editing applications on rigid solids at moderate fields and MAS rates. These parameters have been used and tested in applications to many coals and polymers as well as on model systems.

Methods which employ homonuclear decoupling sequences require additional care in spectrometer alignment. For these methods one must more carefully adjust all rf levels, and pay especial attention to rf homogeneity. In practice one must follow the same procedures as used to prepare for a ^1H CRAMPS experiment. Similar complications from the interaction of the MAS and the MPD also occur as found in CRAMPS.

The majority of the methods that have been discussed here rely on differences in the dipolar coupling networks found between the various CH_n groups. These are washed out when there is significant motional averaging, and as such

all of these methods have limitations. On the other hand, such motional narrowing has many signatures which are easy to recognize, and provides another means of discriminating between resonances in a complex spectrum. When very fast MAS rates are employed, the spin dynamics also change.¹⁷ Most methods presented here work best at low to moderate MAS rates (5 kHz or below). Additional complications can arise at high fields because of the CSA spinning sidebands. Since different molecular orientations with respect to the rotor contribute more intensity to some sidebands than others, the inhomogeneous nature of the CP dynamics can be accentuated. Under many editing schemes the center and sidebands can then behave differently, complicating analysis. In the light of these difficulties, most applications to complex systems have employed low field operation ($B_0 < 4\text{ T}$). Additional work is needed to delineate how high-field and high-speed MAS operation can be accommodated with the majority of these methods.

5 SUMMARY

At present there are many methods available for distinguishing $\text{CH}_3 + \text{CH}_0$ groups from CH and CH_2 centers in CP MAS spectra. A number of reliable approaches for separating CH and CH_2 groups have also appeared, and some of these have been combined in complete spectral editing protocols which separate resonances by multiplicity. These methods have many applications in organic geochemistry and polymer science. Further advances are required before most of these techniques can be combined with operation at the highest available field strengths and spin rates.

Acknowledgments

I wish to acknowledge the especially important contributions of two of my colleagues in this field. The first is Dr Gretchen Webb, my first graduate student, who was instrumental in working out 2D MAS SLF methods for editing, as well as developing much of the hardware that

still makes these experiments work so well in our laboratory. The second is Dr Xiaoling Wu, my long-time associate, collaborator, and friend. It is because of Xiaoling's experimental acumen and theoretical insight that our laboratory has been able to contribute so successfully to the development of spectral editing methods for solids.

1 INTRODUCTION

In the ideal situation for applying NMR spectroscopy, a homogeneous solution is placed inside a homogeneous external magnetic field, leading to single and narrow resonances for each non-equivalent NMR-active nucleus contained in the sample. However, this paradise is almost never reached. Whenever the sample is a liquid crystal, a solid or a slowly reorienting macromolecule, and/or when the magnetic field is not perfectly homogenous within the sample, usually unwanted spinning sidebands appear, flanking the relevant peaks at integral multiples of the sample spinning frequency. The presence of sidebands causes two main problems: (1) a decrease in the height of the central peak, since the overall signal intensity is distributed among the components of the sideband manifold, and (2) a possibility of sidebands overlapping with other interesting peaks, thereby complicating the spectral analysis.

However, sidebands usually contain useful information. The intensity distribution varies according to the sample spinning speed and to the changes of the chemical shift and/or relevant dipolar interactions and/or quadrupolar interactions across the sample. Particularly interesting are the effects observed in high-resolution magic-angle spinning (MAS) NMR spectroscopy, which is the standard technique to analyze powdered solid samples. Suitable analysis of the intensities may allow the characterization of the shielding and/or dipolar and/or quadrupolar tensor(s) affecting the studied nucleus. This explains why a considerable effort has been devoted to the theoretical calculation of sideband intensities, to the development

of methods capable of extracting such information, and to their use for many different nuclei and for a variety of chemical systems.

In the present review, methods for retrieval of the principal components of the relevant tensors from MAS NMR spectroscopic data are revisited, along with suitable analysis of the experimental errors affecting them. Also, a range of applications for structural and dynamic problems is briefly covered. The article builds on the paper by Herzfeld¹ (see **Sideband Analysis in Magic Angle Spinning NMR of Solids**, Volume 7, which was relatively short, though it contained the plots for the graphical method). We will not, herein, describe spinning-sideband analysis for quadrupolar nuclei or for two-dimensional experiments or for situations of rotational resonance. The article will also be restricted to sample-spinning about the magic angle (i.e., VAS or variable angle spinning situations will not be treated). However, cases where dipolar interactions with quadrupolar nuclei affect spinning sidebands for spin-1/2 nuclei will be discussed.

2 THEORY

2.1 The Approach of Maricq and Waugh²

We commence with a discussion of the simplest situation, where only shielding is under consideration. The shielding tensor σ is of second-rank, with principal components defined in the principal axis system (PAS) as σ_{11} , σ_{22} and σ_{33} . These components are labeled in such a way that

$$|\sigma_{33} - \sigma_{\text{iso}}| \geq |\sigma_{11} - \sigma_{\text{iso}}| \geq |\sigma_{22} - \sigma_{\text{iso}}| \quad (1)$$

where $\sigma_{\text{iso}} = (\sigma_{11} + \sigma_{22} + \sigma_{33})/3$ is the isotropic chemical shift. In the σ scale, more positive values correspond to lower resonance frequencies, i.e., increased shielding (notice that $\sigma - \sigma_{\text{ref}} = -\delta$).

It is customary to define the parameters $\Delta\sigma$ (shielding anisotropy) and η (asymmetry parameter) in order to characterize the σ tensor as

$$\Delta\sigma = \sigma_{33} - (\sigma_{11} + \sigma_{22})/2 \quad (2)$$

$$\eta = (\sigma_{22} - \sigma_{11})/(\sigma_{33} - \sigma_{\text{iso}}) \quad (3)$$

Sideband intensities in MAS NMR have been calculated by a number of methods. A general review of numerical simulation of solid-state NMR experiments, including those for rotating samples, has appeared.³ We present here a brief derivation of Maricq and Waugh's equations,² and show how intensities can be conveniently calculated from the latter, in order to introduce computer programs for retrieving the tensor components.

For a single nucleus within a static microcrystalline sample, the shielding Hamiltonian is given in the high-field case by

$$\hbar^{-1}\hat{\mathcal{H}} = -\omega_0\sigma_{zz}\hat{I}_z \quad (4)$$

where ω_0 is the resonance frequency in angular units and σ_{zz} is the appropriate component of the σ tensor relating the spin component I_z and the magnetic field B_0 (assumed to point

along the z axis). The required σ_{zz} component is obtained from the diagonal σ tensor (as defined in its PAS)

$$\sigma = \begin{pmatrix} \sigma_{11} & 0 & 0 \\ 0 & \sigma_{22} & 0 \\ 0 & 0 & \sigma_{33} \end{pmatrix} \quad (5)$$

In order to obtain σ_{zz} in a MAS experiment, the tensor σ is subjected to the following transformations: (1) from its PAS to the MAS frame (where the z axis coincides with the spinning axis), and (2) from the latter frame to the laboratory (LAB) frame (where the z axis is coincident with $\mathbf{B}_0$). The latter rotations are accomplished by using the following sets of Euler angles: (α, β, γ) for the first rotation, and $(\psi, \xi, 0)$ for the second. Now $\psi = \alpha_0 + \omega_r t$, where ω_r is the sample spinning frequency, and ξ is the angle between $\mathbf{B}_0$ and the spinning axis, i.e., $\xi = 54.7^\circ$ for the magic-angle situation (Figure 1)*. Therefore

$$\begin{aligned} \sigma(\text{MAS}) &= \mathbf{R}_z(\gamma)\mathbf{R}_x(\beta)\mathbf{R}_z(\alpha)\sigma(\text{PAS})\mathbf{R}_z^{-1}(\alpha)\mathbf{R}_x^{-1}(\beta)\mathbf{R}_z^{-1}(\gamma) \\ \sigma(\text{LAB}) &= \mathbf{R}_x(\xi)\mathbf{R}_z(\psi)\sigma(\text{MAS})\mathbf{R}_z^{-1}(\psi)\mathbf{R}_x^{-1}(\xi) \end{aligned} \quad (6)$$

where $\mathbf{R}$ are generalized rotation matrixes, the rotation axes are denoted as subscripts, and the rotation angles are in parentheses.

The result is

$$\begin{aligned} \sigma_{zz} &= \sigma_{\text{iso}} + \frac{2}{3} \left[\frac{\cos 2\psi'}{2} (\sigma'_{22} - \sigma'_{11}) + \sin 2\psi' \sigma'_{12} \right] \\ &+ \frac{2\sqrt{2}}{3} (\sigma'_{13} \sin \psi' + \sigma'_{23} \cos \psi') \end{aligned} \quad (7)$$

where

$$\psi' = \psi + \gamma \quad (8)$$

$$\sigma'_{22} = (\sigma_{11} \sin^2 \alpha + \sigma_{22} \cos^2 \alpha) \cos^2 \beta + \sigma_{33} \sin^2 \beta \quad (8)$$

$$\sigma'_{11} = \sigma_{11} \cos^2 \alpha + \sigma_{22} \sin^2 \alpha \quad (9)$$

$$\sigma'_{12} = (\sigma_{11} - \sigma_{22}) \sin \alpha \cos \alpha \cos \beta \quad (10)$$

$$\sigma'_{13} = (\sigma_{11} - \sigma_{22}) \sin \alpha \cos \alpha \sin \beta \quad (11)$$

$$\sigma'_{23} = (\sigma_{11} \sin^2 \alpha + \sigma_{22} \cos^2 \alpha) \sin \beta \cos \beta - \sigma_{33} \sin \beta \cos \beta \quad (12)$$

Notice from equation (7) that σ_{zz} is time dependent, and oscillates with frequencies 0, $\omega_r t$ and $2\omega_r t$ ($\psi = \omega_r t$). Hence the shielding becomes time-dependent. Since the relevant Hamiltonian $\hat{\mathcal{H}}$ commutes with itself at all times, the propagator $U(t)$ of the spin system is given by $U(t) = \exp[i\hbar^{-1} \int_0^t \hat{\mathcal{H}}(t) dt]$. Therefore, the time-dependent FID can be written as^{1,2}

$$f(t) = f_0 \exp[i\theta(t)] \quad (13)$$

where

$$\theta(t) = \int_0^t \omega_0 \sigma_{zz}(t) dt \quad (14)$$

* An alternative but equivalent approach is the use of Wigner rotation formulae. For a discussion, see B.C. Gerstein and C.R. Dybowski, 'Transient Techniques in NMR of Solids', Academic Press, 1985.

Figure 1 (a) mutual relationship between the magic-angle spinning frame (MAS) and the frame defined by the principal components of the shielding tensor. (b) orientation of the spinning axis with respect to the external magnetic field

Integrating equation (14) for a MAS cycle yields¹

$$\begin{aligned} \theta(t) &= \omega_0 \left\{ \sigma_{\text{iso}} t + \frac{1}{3\omega_r} \left[\frac{\sin 2\psi'}{2} (\sigma'_{22} - \sigma'_{11}) - \cos 2\psi' \sigma'_{12} \right] \right. \\ &+ \frac{2\sqrt{2}}{3\omega_r} (\sigma'_{23} \sin \psi' - \sigma'_{13} \cos \psi') - \\ &- \frac{1}{3\omega_r} \left[\frac{\sin 2\gamma}{2} (\sigma'_{22} - \sigma'_{11}) - \cos 2\gamma \sigma'_{12} \right] \\ &\left. + \frac{2\sqrt{2}}{3\omega_r} (\sigma'_{23} \sin \gamma - \sigma'_{13} \cos \gamma) \right\} \end{aligned} \quad (15)$$

Frequency information can be gathered from equations (13–15) by applying a Fourier transformation. Since $\theta(t)$ is periodic (with period $2\pi/\omega_r$), the observed spectrum will consist of peaks centred at $(\omega_0 \sigma_{\text{iso}} + k\omega_r)$, where k is an integer (positive or negative). The corresponding Fourier coefficients provide the amplitudes F_k of the frequency components, and are given by:

$$F_k = \frac{1}{2\pi} \int_0^{2\pi} \exp[i(k\psi + A_2 \sin 2\psi + B_2 \cos 2\psi + A_1 \sin \psi + B_1 \cos \psi)] d\psi \quad (16)$$

$$A_1 = 2\sqrt{2}\omega_0 \sigma'_{23} / (3\omega_r) \quad (17)$$

$$A_2 = \omega_0 (\sigma'_{22} - \sigma'_{11}) / (6\omega_r) \quad (18)$$

$$B_1 = -2\sqrt{2}\omega_0\sigma'_{13}/(3\omega_r) \quad (19)$$

$$B_2 = -\omega_0\sigma'_{12}/(3\omega_r) \quad (20)$$

The peak intensities are obtained from the squared modulus $|F_k|$.¹ However, it should be noticed that the above discussion corresponds to a single nucleus whose σ tensor is oriented in the LAB frame according to the angles (α, β, γ) . For a microcrystalline sample, therefore, the peak intensities are given by the following powder average¹

$$I_k = \frac{1}{4\pi} \int_0^\pi \int_0^{2\pi} |F_k|^2 d\alpha \sin\beta d\beta \quad (21)$$

An approximate method of calculation based on the above equations has been discussed, which uses a series expansion, and does not require the computation of integrals such as those in equation (21).⁴ This method is accurate for values of $\omega_0\Delta\sigma/\omega_r$ up to ca. 3. However, better accuracy is obtained by employing computer-based approaches to calculate each sideband at a time, using equation (21), while an alternative method consists of calculating the FID [equation (13)] and then performing a computer Fourier transformation. In the latter approach, the Fourier transform contains the intensities of all sidebands at the same time. Spinning sideband manifolds arising from paramagnetic shift anisotropy can be similarly calculated.⁵ When overlapping peaks occur, it may be useful to apply maximum entropy deconvolution before spinning sideband intensities are calculated, in order to isolate different sideband manifolds which would otherwise be unresolvable,⁶ though in principle direct fitting of the complete sidebands, including their shapes, may be better.

The range of applicability of the above equations should be mentioned. As explained above, equation (21) applies to cases where the spin Hamiltonian commutes with itself at all times. These include, besides the case of a single non-interacting nucleus, other situations such as: (1) nuclei subjected to heteronuclear dipolar or indirect coupling interactions and (2) nuclei under homonuclear AX-type dipolar or indirect interactions (see below). Conversely, the above approach is no longer applicable when strongly coupled homonuclear interactions occur.

2.2 Other Approaches

When homonuclear interactions occur, and provided the coupled pairs of nuclei are isolated, one can apply Floquet theory, average Hamiltonian theory or a numerical evaluation of the spin density matrix in order to calculate the sideband intensities.⁷⁻¹³ An interesting example is provided by the ^{31}P , ^{31}P coupling in a phosphole tetramer and in an *ortho* diphosphino benzene derivative, where information concerning the orientations of the phosphorus chemical shift tensors and the sign of $J(^{31}\text{P}, ^{31}\text{P})$ have been deduced.⁹

Another area where the above theory cannot be applied is when chemical exchange takes place in the intermediate regime (i.e., when the exchange rates are comparable to the difference in frequency between the exchanging σ tensors). Here again a Liouville treatment of the exchange, together with Floquet theory, can successfully account for the sideband intensities.¹⁴⁻¹⁶ However, it should be noticed that, for rapidly exchanging systems, the equations of Maricq and Waugh² can

be confidently applied by considering the nuclei under the influence of an effective tensor σ_{eff} given by a population-weighted average of the contributing σ tensors. Pertinent examples of this latter situation are illustrated by the fast solid-state proton transfer taking place between individual phosphate units in the dihydrogen phosphates,¹⁷ in the phosphoric acid:urea adduct¹⁸ and in the complexes formed by phenols and a phosphine oxide.¹⁹

For homonuclear coupling interactions which are extended to the whole sample, none of the above methods can be applied. Two such cases are worth of mention: (1) the effect of ^1H , ^1H dipolar coupling on ^1H spinning sideband intensities of hexamethylbenzene, which has been related to M_n dipolar moments ($n = 2, 4, 6$ and 8),²⁰ and (2) dipolar ^{31}P , ^{31}P coupling in MH_2PO_4 phosphates ($\text{M} = \text{K}^+, \text{Rb}^+$ and NH_4^+), accounted for by assuming that the ^{31}P nuclei are acting as if they were non-equivalent, and that the coupling extends to only a nearest neighbor sphere.^{21,22}

3 RETRIEVAL OF TENSOR PARAMETERS

In this Section we review the methods which are usually employed for retrieving tensor parameters from sideband intensities when the equations of Maricq and Waugh¹ apply, again using the notation for a simple shielding case. This is also relevant to cases where intensities are not solely determined by the shielding tensor σ , but also by effective tensors resulting from the interplay of the latter with other relevant interactions (see below).

Several approaches have been described in the literature in order to retrieve shielding tensor parameters from sideband intensities. One of them is Maricq and Waugh's method of moments,² in which the computation of the second and third moments M_2 and M_3 respectively allows the parameters $\Delta\sigma$ and η to be obtained by solving the following system of equations

$$8(\Delta\sigma)^3 - 30M_2(\Delta\sigma) - 35M_3 = 0 \quad (23)$$

$$\eta^2 = 1 - 35M_3/2(\Delta\sigma)^3 \quad (24)$$

where $M_n = \omega_r^n \sum k^n I_k / \sum I_k$. Equations (23) and (24) have three solutions for $\Delta\sigma$, and each of them, in turn, provides two solutions for η . The six pairs of values of $\Delta\sigma$, η correspond to the six possible permutations of the three principal components of the σ tensor. Due to the presence of the factor k^n in the definition of the n th moment, the accuracy of applying the above method depends critically on the intensities of outer sidebands, which are usually small and therefore are the most affected by experimental noise.

To avoid the latter problems, Herzfeld and Berger devised a graphical method based on a relatively small set of accessible sideband intensities.¹ Specifically, they generated plots of the intensity ratios I_k/I_0 ($k \neq 0$) as a function of two parameters, μ and ρ , which conveniently replace $\Delta\sigma$ and η

$$\mu = \omega_0\Delta\sigma(1 + \eta/3)/\omega_r \quad (25)$$

$$\rho = \pm(1 - \eta)/(1 + \eta/3) \quad (26)$$

Since the plots are based on ratios of intensities rather than on absolute values of I_k , the latter need not be normalized.

Only ratios involving experimentally accessible values of I_k are considered. The method is based on localizing the values of μ and ρ for which the experimental intensity ratios closely match the theoretical ones.¹ Additionally, a qualitative view of the errors in estimating the retrieved parameters can be obtained by comparing the shielding tensors calculated from different values of k . Neither the moments method nor the graphical method of Herzfeld and Berger are now greatly used.

The generalized use of computers in the chemical laboratory has led to convenient computer-based methods for obtaining shielding parameters (or ‘paramagnetic shift anisotropies’⁵), mainly based on iterative methods.^{23–26} Figure 2 shows an example.^{27,28} In such cases one starts from a given set of initial parameter guesses (these can be the Herzfeld-Berger parameters μ and ρ , or directly $\Delta\sigma$ and η), and refines them iteratively, using standard routines for non-linear parameter estimation. Simplex or Newton-Gauss methods are used to minimize the standard deviation s_{fit} (or, alternatively, χ^2)

$$s_{\text{fit}} = \left\{ \frac{[I_k(\text{calc}) - I_k(\text{exp})]^2}{(n - 2)} \right\}^{\frac{1}{2}} \quad (28)$$

where n is the number of experimentally accessible sidebands.

Computer-based methods which use the full sideband manifold are considered to be the most reliable ones. However, the choice of the optimum number of sidebands to obtain for fitting (i.e., the decision as to the best value of ω_r) is a matter for discussion.²⁹ The software packages from the Varian and Bruker manufacturers now contain programs for spinning sideband analysis. A ^{119}Sn example³⁰ of ssb fitting using the STARS program³¹ is shown in Figure 3.

The use of Floquet theory for calculating spinning sideband manifolds has been reviewed.³² A further method, described

by Fenzke et al.,³³ generates a series of computer files from equation (22) for values of μ, ρ in the ranges (0,20) and (−1,1) respectively, containing the theoretical sideband intensities, with k ranging from −10 to 10 (this may constitute a drawback of the method, although one may produce files for a larger ranges of μ, ρ and k). From a measured set of experimental intensities, a statistical error indicator $\varepsilon = 1 - [\sum I_k(\text{calc})I_k(\text{exp})]/\sum I_k^2(\text{calc})\sum I_k^2(\text{exp})$ is computed, and a computer search is made for the values of μ and ρ which lead to its minimum value. A plot of this error indicator as a function of μ, ρ in the vicinity of the minimum provides an estimation of the experimental errors. Figure 4 gives such a three-dimensional plot of ε as a function of μ and ρ for the case of the $^{12}\text{H}_7$ -urea/phosphoric acid adduct.¹⁸ The projection of the plot onto the μ, ρ plane (Figure 4b) gives a qualitative view of the fitting errors.

4 ERROR ANALYSIS

Two sources of errors should be considered in retrieving shielding parameters from MAS sideband intensities: (1) experimental errors leading to observed sideband intensities which deviate from those theoretically expected, and (2) computer-fitting errors, which depend on the characteristics of the minimization procedure, and also on the shielding parameters themselves.

A number of publications have considered several experimental factors affecting the accuracy in the derived parameters.^{24,25,30,33,34} When using cross-polarization methods, for example, variations of the polarization efficiency with the orientation within the sample may be a source of error. This error stems from the anisotropy of the Hartmann-Hahn mismatch.²⁵ To overcome this problem, use of a modified pulse

Figure 2 Example of the iterative fitting of a ^{13}C spinning sideband manifold, obtained at a spin rate of 1.3 kHz using an in-house computer program.²⁸ The C22 band of Form II of cortisone acetate is illustrated.²⁷ The vertical arrow indicates the centerband. The solid line (to which the shift scale refers) represents the experimental spectrum, while the dashed line (arbitrarily offset) is as computer-fitted with the parameters $\zeta = -78$ ppm, $\eta = 0.49$. (Note: (a) these values differ slightly from those in Table 2 of Ref.²⁷ and (b) Figure 2 of Ref.²⁷ incorrectly refers to C5 rather than C22.) (Reproduced by permission from E. A. Christopher, R. K. Harris and R. A. Fletton, *Solid State NMR*, 1992, 1, 93)

Figure 3 (a) Computed-fitted and (b) experimental (111.9 MHz) $^{119}\text{Sn}\{-^1\text{H}\}$ spinning sideband patterns for tin sulfate. The parameters obtained by the use of the Varian STARS program are $\zeta = 553$ ppm, $\eta = 0.14$. The rotation rate was 9.0 kHz. The fitting is carried out with a constant linewidth, so the peak-heights of (a) and (b) do not necessarily match well. The integrals and the differences between experimental and simulated values are plotted to the right, the horizontal dashed line being at zero level

sequence called multiple-contact isotropic cross-polarization (MCICP) has been proposed, together with an empirical intensity correction function.²⁵ On the other hand, for single-pulse excitation (direct polarization), an important factor is the variation in the degree of polarization of the nuclei over the full frequency range of the spectrum, as a result of the finite duration of the pulse used in the excitation process.^{31,34} This latter problem becomes serious for heavy nuclei such as ^{199}Hg , for which shielding anisotropies of thousands of ppm may occur. Attempts have been made to correct for these deviations by utilizing the theoretical RF field amplitude as a function of frequency.

The estimation of fitting errors has been discussed several times,^{24–26,35,36} and in special detail in a recent publication.³⁷ Once the best-fit parameters and the standard deviation s_{fit} (equation (28)) are obtained by the program, one may estimate the errors in $\Delta\sigma$ and η by computing the so-called marginal standard deviations

$$s_{\text{marg}}(i) = s_{\text{fit}}[(B^{-1})_{ii}]^{1/2} \quad (29)$$

where B is a covariance matrix defined as $B_{ij} = \sum [dI_k(\text{calc})/di][dI_k(\text{calc})/dj]$, and i, j are refined parameters. Additionally, the following ratio of variances is useful in assessing whether the parameters are properly defined by the experimental intensities

$$R_i = \frac{(B^{-1})_{ii}}{(B_{ii})^{-1}} \quad (30)$$

Another recent article²⁹ has considered the accuracy of tensor parameters measured using solid-state NMR and has used a similar approach. Comparison to the static limit

shows that the determination of the anisotropy is more reliable in spinning experiments than in static ones, and an optimum number of sidebands has been found for which the estimation of the anisotropy is the most accurate. However, an analogous analysis for the asymmetry parameter shows it to be consistently more reliably determined from a static spectrum.

In fact, it has been pointed out several times^{28,36–38} that the uncertainty in asymmetry values derived from ssb analysis is very high when the magnitude is low. Indeed, it becomes difficult to distinguish axial symmetry from non-axial cases when $\eta < 0.2$. The comparison of R_i with critical values of F from standard statistical tables allows one to determine if the parameters have been adequately modelled.³⁷ However, though the parameters may appear to be well defined, the standard errors in η may be too high to draw definite conclusions regarding axially. This problem is highlighted when the value of the ratio $\omega_0\Delta\sigma/\omega_r$ is sufficiently small.³⁷

Questions of errors and correlations between parameters have also been discussed by Skibsted et al.³⁹ They have illustrated contour plots of rms deviations between experimental and simulated intensities for the spinning sidebands in the ^{133}Cs MAS spectrum of CsVO_3 , but the emphasis in their work is on the interplay of shielding and quadrupolar tensors.

5 INTERPLAY OF TENSORS

In many cases, more than one type of tensor will affect static NMR bandshapes and hence spinning sideband manifolds. The matter is relatively simple when only inhomogeneous interactions are involved since these can be considered to contribute independently to the Hamiltonian. It is instructive to consider the simplest situation involving three such tensors,

Figure 4 Minimization graphs relevant to ^{31}P spinning sideband analysis for the $(^2\text{H}_7)$ -urea phosphoric acid adduct¹⁸: (a) Plot of ε as a function of μ, ρ . (b) Projection of the plot onto the μ, ρ plane for a closer inspection of the minimum

namely shielding, dipolar coupling and indirect ('scalar') coupling. The influence of a sufficiently large isotropic indirect coupling constant is necessary in order to give resolvable sub-spectra of spinning sideband manifolds (see below), which allows spectral analysis to proceed. In this section a common alternative definition of anisotropy to that given in equation (2) will be used, namely

$$\zeta = \sigma_{33} - \sigma_{\text{iso}} \quad (31)$$

It is clear that the two definitions are equivalent, with $\Delta\sigma = 3\zeta/2$.

5.1 Interplay of σ , D and J ^{40–43}

The simplest case, which illustrates the essential features, occurs for isolated heteronuclear two-spin (AX) systems with $I_A = I_X = 1/2$, in which axial symmetry prevails, so that

asymmetry in σ and J can be ignored. All three tensors for, say, the A spins, are co-axial (with the major principal axis along the internuclear A, X distance, r_{AX}), and the anisotropy in J has exactly the same form as the dipolar coupling, D , so that an effective parameter D' may be defined as

$$D' = D - \frac{\Delta J}{3} \quad (32)$$

where D is the dipolar coupling constant in frequency units, $(\mu_0/4\pi)\gamma_A\gamma_X\hbar/2\pi r_{AX}^3$, and ΔJ is the anisotropy in J (see **Dipolar & Indirect Coupling Tensors in Solids, Volume 3; Indirect Nuclear Spin-Spin Coupling Tensors**) expressed as $J_{\parallel} - J_{\perp}$. Note that this implies that there is no NMR experimental method which is able to separate D and ΔJ . The discussion will proceed under the assumption that γ_A and γ_X are both positive, but the results can be readily adjusted if this is not the case. The NMR Hamiltonian may be written as

$$\begin{aligned} h^{-1}\hat{\mathcal{H}} = & -\nu_A^0 \left[1 - \left\{ \sigma_A^{\text{iso}} + \frac{1}{2}\zeta_A (3\cos^2\theta - 1) \right\} \right] \hat{I}_{zA} \\ & -\nu_X^0 \left[1 - \left\{ \sigma_X^{\text{iso}} + \frac{1}{2}\zeta_X (3\cos^2\theta - 1) \right\} \right] \hat{I}_{zX} \\ & + J_{AX}^{\text{iso}} \hat{I}_{zA} \hat{I}_{zX} - D'(3\cos^2\theta - 1) \hat{I}_{zA} \hat{I}_{zX} \end{aligned} \quad (33)$$

where $\nu_A^0 = \gamma_A B_0/2\pi$ and $\nu_X^0 = \gamma_X B_0/2\pi$ are the A and X Larmor frequencies in the absence of shielding, σ_A^{iso} and σ_X^{iso} are the isotropic A and X shielding constants, ζ_A and ζ_X are the shielding anisotropies expressed as $\sigma_A^{\parallel} - \sigma_A^{\text{iso}}$ and $\sigma_X^{\parallel} - \sigma_X^{\text{iso}}$, respectively, J_{AX} is the isotropic (A, X) coupling constant and θ is the angle between $\mathbf{r}_{AX}$ and $\mathbf{B}_0$. The transitions of the A nucleus are therefore described by

$$\begin{aligned} \nu_A = & \nu_A^0 \left[1 - \left\{ \sigma_A^{\text{iso}} + \frac{1}{2}\zeta_A (3\cos^2\theta - 1) \right\} \right] \\ & - J_{AX} m_X + D'(3\cos^2\theta - 1) m_X \end{aligned} \quad (34)$$

where m_X is the appropriate spin component quantum number for the X spin. This equation reduces to

$$\nu_A = \nu_A^{\text{iso}} - \frac{1}{2}\nu_A^0 \zeta_A^{\text{eff}} (3\cos^2\theta - 1) - J_{AX} m_X \quad (35)$$

where ζ_A^{eff} is an effective tensor anisotropy given by

$$\zeta_A^{\text{eff}} = \zeta_A - \frac{2D'm_X}{\nu_A^0} \quad (36)$$

The A transitions therefore form two sub-spectra ($m_X = \pm\frac{1}{2}$), in one of which the shielding and dipolar tensors reinforce one another whereas in the other they partially cancel

Figure 5 Proton-decoupled ^{19}F CPMAS NMR spectrum of $(\text{Ph}_2\text{FPNMe})_2$ at 188 MHz, and spin rate 6 kHz showing the difference in centerband intensities of the two doublet components, arising from the 'squeezing' and 'stretching' of the relevant subspectra. (Figure adapted from that in R. K. Harris and L. A. Crowe, *J.C.S. Dalton*, 1999, 4315, with permission)

each other. Thus one static powder subspectrum is 'stretched' whereas in the other is 'squeezed'.

Under slow MAS conditions, the influence of the angle-dependent term $3\cos^2\theta - 1$ is translated into a distribution of intensities among the relevant spinning sidebands, which extend over a larger frequency range for the 'stretched' subspectrum than for the 'squeezed' subspectrum. The isotropic coupling serves to resolve the subspectra, enabling the spinning sideband manifolds to be analysed separately, thus yielding the two values of ζ_A^{eff} . One consequence is that the centerbands of the two components, split by J_{AX} , have different intensities (see Figure 5).⁴⁴ The magnitudes of ζ_A , D' and J_{AX} are readily obtained by the analysis. Since the sign of ζ_A will normally be obvious (and can be obtained separately by spinning sideband analysis of an A spectrum obtained with X-decoupling) sign information on J_{AX} and D' are obtained, albeit with some ambiguity. Only the relative signs of D' and J_{AX} are determined, the rule being as follows: If the high-frequency spinning sideband manifold has the larger magnitude of ζ_A^{eff} , then (i) for positive ζ_A , D' and J_{AX} have the same sign, whereas (ii) for negative ζ_A , D' and J_{AX} have opposite signs. The inverse is true if the larger magnitude of ζ_A^{eff} belongs to the low-frequency subspectrum. If r_{AX} is known (e.g., from diffraction studies), D can be calculated, so ΔJ can be derived, though with an ambiguity unless the sign of J_{AX} is known. On the other hand, if the relative magnitudes of D and $\Delta J/3$ can be assumed, the absolute sign of J_{AX} can be determined.^{40,42}

The extension to a linear AX_2 case is straightforward. There will now be three spinning sideband manifolds in the A spectrum, with effective tensor anisotropies given by

$$\zeta_A^{\text{eff}} = \zeta_A - \left(\frac{2D'}{v_0} \right) \sum m_X \quad (37)$$

where $\sum m_X = 1, 0$ or -1 , associated with centerbands at $\nu_A^{\text{iso}} - J_{\text{AX}} \sum m_X$. The central sideband manifold gives ζ_A

directly, because it is independent of D' . Clearly this is an advantage, particularly if A-{X} spectra cannot be obtained because of spectrometer limitations.

Zilm and Grant⁴⁵ derived expressions for heteronuclear two-spin (AX) solid-state spectra of static samples, and these have been adapted for MAS cases and further discussed by Harris et al.⁴⁰ and Haubenreisser et al.⁴¹ The theory involved can form the basis of a computer program involving the Euler angles between the tensor axes. This has been done by Cherryman and Harris⁴³ for the AX and AX_2 cases, though still under the assumptions that J is axially symmetric and co-axial with D . These authors analysed the spectra to triple-fit the coupled and A-{X} decoupled spectra of the AX case (see Figure 6) simultaneously (and correspondingly for the three subspectra of the AX_2 case). Triple fitting can also be carried out for spectra with satellite peaks arising from isotopic mixtures, e.g., for ^{19}F spectra influenced by coupling to ^{119}Sn ^{42,45} or for ^{31}P spectra of compounds exhibiting ^{31}P , ^{195}Pt coupling.⁴⁶ Recently, errors in the simultaneous fit of shielding tensor components and in the Euler angles which fix the orientation of the tensor in the molecular frame have been discussed, and clues have been given concerning the experimental variables to be set in order to obtain the desired accuracy in the orientation angles.⁴⁷

Cases involving homonuclear coupling (dipolar and indirect) together with shielding are more complex and have been mentioned briefly above, references 9 and 10 supplying ideal cases.

Practical application of the above theory has been made for the two-spin (^{13}C , ^{31}P) case,^{40,41} for the two-spin (^{119}Sn ,

Figure 6 Proton-decoupled ^{119}Sn CPMAS NMR spectra of $n\text{Bu}_3\text{SnF}$ at 74.6 MHz and spin rate 4 kHz. (a) Triple-resonance case (i.e., ^{19}F -decoupled). (b) Spectra with fluorine coupling effects to show the three subspectra. Triple-fit procedures for the spinning sideband patterns shown in (b) give tensor information which, for the shielding interaction, are consistent with those derived from (a). (Reproduced by permission from J. C. Cherryman and R. K. Harris, *J. Magn. Reson.*, 1997, **128**, 21)

^{19}F) situation,⁴³ and for $(^{119}\text{Sn}, ^{19}\text{F})$ AX_2 spectra.^{42,43} The lack of observable differences in intensity distribution between spinning sideband manifolds of subspectra arising from $(^{195}\text{Pt}, ^{31}\text{P})$ indirect coupling has been taken⁴⁸ as evidence that ^{195}Pt shielding anisotropy dominates over dipolar coupling in *cis*- $\text{PtMe}_2(\text{PPh}_3)_2$.

5.2 Interplay of σ , D and q ^{49–51}

For spin-1/2 nuclei coupled to quadrupolar spins, second-order effects occur because the influence of the quadrupolar interaction is transferred to the spin-1/2 by the coupling (see **Magic Angle Spinning Carbon-13 Lineshapes: Effect of Nitrogen-14**, Volume 5; **Magic Angle Spinning: Effects of Quadrupolar Nuclei on Spin-1/2 Spectra**, Volume 5). This has two effects: (i) it alters the multiplet splittings which would otherwise be equal to $|J_{\text{AX}}|$, and (ii) it causes each multiplet peak to be a powder pattern (see Ref.⁵² for a review). Such complications do not affect the spinning sideband analysis described above as long as the multiplet components are clearly resolved (and provided integrals rather than peak heights are used as intensities since the powder patterns vary in shape). Thus, similar principles to those of the above Section can be invoked for AX cases in which dipolar coupling is between the observed spin-1/2 and a single quadrupolar nucleus. Equation (35) can still be used, but now m_X takes $2I + 1$ possible values ($m_X = I, I - 1, I - 2, \dots, -I$), resulting in $2I + 1$ subspectra. Clearly spinning sideband analysis becomes more accurate since the number of parameters involved is the same as for two spin-1/2 nuclei. Such spectra have been examined⁴⁹ for $(^{31}\text{P}, ^{55}\text{Mn})$, $(^{31}\text{P}, ^{59}\text{Co})$ and $(^{31}\text{P}, ^{93}\text{Nb})$ spin systems (Figure 7).

However, this simple situation is seldom true for ^{13}C spectra involving $(^{13}\text{C}, ^{14}\text{N})$ spin pairs, since in this case the relevant isotropic indirect coupling constants are generally small, even negligible. The powder patterns for the subspectra involving $m_N = \pm 1$ overlap, giving a 2:1 or 1:2 appearance to the spectrum in the limit of fast spinning. However, the powder bandshapes will vary over the spinning sideband manifold,⁵⁰ so that in the simplest situation,

Figure 7 Phosphorus-31 direct polarization spectrum of $\text{Mn}_2(\text{CO})_9\text{PPh}_3$ at 121.4 MHz showing the differences in spinning sideband intensities for the subspectra from the multiplet components (arising from ^{55}Mn , ^{31}P coupling) because of the interplay between the shielding, quadrupolar and indirect coupling tensors. (Reproduced by permission from R. Gobetto, R. K. Harris and D. C. Apperley, *J. Magn. Reson.*, 1992, **96**, 119)

Figure 8 Centerband and sidebands for the high-frequency cyanide ^{13}C CPMAS signals of $(\{(\text{CH}_3)_3\text{Pb}\}_4\text{Ru}(\text{CN})_6)$ at 75.4 MHz. i.e., when σ , D and q are axially symmetric and co-axial, the angle β between their unique axes and the spinning axis becomes an important variable. The theory has been discussed by Davies et al.⁵⁰ and applied (using a perturbation approach) to the cyanide carbon signals of a coordination polymer, $[\{(\text{CH}_3)_3\text{Pb}\}_4\text{Ru}(\text{CN})_4]_\infty$ (see Figure 8). The shape of the centerband at infinite spinning speed is dominated by the intensities of the major singularities at $\beta = 54.7^\circ$ and 90° . As the rotation rate is lowered, the former loses intensity in comparison to the latter. The splitting of the centerband therefore apparently increases as the rotation speed decreases (see Figure 9). There are concomitant changes in the shapes of the spinning sidebands. Their patterns and their intensities can be simulated using standard theory,⁵³ and therefore information on ζ_{C} , D_{CN} (in principle, D') and q obtained. Off-MAS ^{13}C spinning sideband manifolds for the cyanide signal of CH_3CN have also been simulated,⁵¹ and used together

Figure 9 (a) calculated bandspace for an asymmetric 2:1 splitting produced by residual second-order ^{13}C , ^{14}N dipolar coupling. The peaks associated with the orientations $\beta = 90^\circ$ and 54.7° (where β is the angle made by the unique axes of the co-axial tensors σ , D and q with the spinning axis) are indicated by arrows. (b) calculated (normalized) centerband intensities for crystallites with $\beta = 90^\circ$ and 54.7° as a function of the ratio between the shielding anisotropy (expressed in Hz) and the spinning frequency. with other NMR spectra to yield detailed data on σ , D and q .

Ding and McDowell⁵⁴ have pointed out the limitations of most calculations of spectra involving coupling between spin-1/2 and quadrupolar nuclei. They give a general and exact description of the problem within the framework of the density matrix, including the spinning sidebands in a natural manner. They apply the theory to ^{13}C spectra of $\text{KPt}(\text{CN})_4 \cdot 3\text{H}_2\text{O}$, including the ^{195}Pt satellites, and show that the complex spectra are fitted extremely well at different spinning rates, yielding the relevant parameters. A density matrix approach has also been used by Amoureux et al.⁵⁵ to produce a general computer program, PULSAR, to simulate a wide range of NMR situations involving interplay of different tensors, including the Euler angles between their axes.

1 INTRODUCTION

When a system is subject to a time-dependent Hamiltonian $\hat{\mathcal{H}}(t)$, it may sometimes happen that its development over some interval (t_1, t_2) could have been caused by a hypothetical time-independent average Hamiltonian. The requirements for this replacement and the circumstances under which it is useful are the subjects of this article. We also exhibit the forms that $\hat{\mathcal{H}}$ takes in several cases of practical importance in NMR.

Consider the following simple example: a spin or group of spins has a frequency shift δ which varies cosinusoidally with time: $\delta(t) = \delta_0 + \alpha \cos \omega t$. The magnetization $\mathbf{m}_0$ is initially placed along the x axis of a rotating frame, after which the FID $g(t)$ depends on the precessional phase accumulation φ :

$$g(t) = \frac{m_x(t)}{m_0} = \cos \varphi(t),$$

$$\varphi(t) = \int_0^t \delta(t') dt' = \delta_0 t + \frac{\alpha}{\omega} \sin \omega t \quad (1)$$

By trigonometric identities and the Jacobi–Anger formula, this gives

$$g(t) = \cos \delta_0 t \left\{ J_0(k) + 2 \sum_{n=0}^{\infty} J_{2n}(k) \cos 2n\omega t \right\}$$

$$- \sin \delta_0 t \sum_{n=1}^{\infty} J_{2n-1}(k) \sin(2n-1)\omega t \quad (2)$$

with $k = \alpha/\omega$. The Fourier transform of equation (2) is the familiar spectrum consisting of a central resonance and an array of sidebands spaced by ω with intensities proportional to the corresponding Bessel functions. The sideband structure is a consequence of the periodicity of $\hat{\mathcal{H}}(t)$.

In practice FIDs are usually sampled at some convenient but otherwise arbitrary interval t_s , anticipating discrete Fourier transformation. The sideband pattern just described is seen if $t_s \ll 2\pi/\omega$. Suppose instead that the data sampling is synchronized with ω and occurs only once in each N periods, $N = 1, 2, \dots$. Substituting $t_s = 2\pi N/\omega$, we see that the

trigonometric functions disappear and $g(t) = g(mt)_s = \cos \delta_0 t$. As a consequence of synchronous sampling, all sidebands have disappeared from the spectrum, having been folded into the center band. The same result is obtained if the oscillating parts of equation (2) are replaced by their averages, namely 0. In quantum mechanical language, the time-dependent spin Hamiltonian has been replaced by a time-independent average Hamiltonian:

$$\hat{\mathcal{H}}(t) = (\delta_0 + \alpha \cos \omega t) \hat{I}_z \rightarrow \hat{\bar{\mathcal{H}}} = \delta_0 \hat{I}_z \quad (3)$$

The requirements of (i) the periodic time dependence of the Hamiltonian and (ii) synchronous sampling are characteristic of average Hamiltonians. It is also typical that in the course of averaging, some part of the original Hamiltonian (here the part containing information about α) is lost and the spectrum is correspondingly simplified.

The example discussed is incomplete in that $\hat{\mathcal{H}}(t)$ was chosen as a single spin operator with a time-dependent scalar coefficient, so that $[\hat{\mathcal{H}}(t), \hat{\mathcal{H}}(t')] = 0$. When this is not so, the meaning of $\hat{\bar{\mathcal{H}}}$ must be modified. In the next section we review the formal theory that deals with these matters.¹

2 MAGNUS EXPANSION

We consider the time development of a quantum state between times 0 and T :

$$|a(T)\rangle = \hat{U}(T, 0)|a(0)\rangle \quad (4)$$

If $\hat{\mathcal{H}}$ were independent of time, we would have simply $\hat{U} = \exp(-i\hat{\mathcal{H}}t)$, but more generally

$$\hat{U}(T, 0) = \mathcal{T} \exp \left\{ -i \int_0^T \hat{\mathcal{H}}(t) dt \right\} \quad (5)$$

where the symbol is a reminder that the infinitesimal propagators

$$\hat{u}(t' + dt, t') = \exp\{-i\hat{\mathcal{H}}(t') dt\} \quad (6)$$

of which $\hat{U}$ is composed must be multiplied together with t' increasing from right to left.

There is no general way of accomplishing this unless $\hat{\mathcal{H}}$ is weak enough or t short enough that not much happens to the system: $\hat{U} \approx 1$, or, informally put, $\hat{\mathcal{H}}t \ll 1$. Normal time-dependent perturbation theory gives a recipe based on repeated iteration of the following pair of relations:

$$|a(T)\rangle = |a(0)\rangle + \int_0^T \frac{\partial |a(t)\rangle}{\partial t} dt, \quad \frac{\partial |a(t)\rangle}{\partial t} = -i\hat{\mathcal{H}}(t)|a(t)\rangle \quad (7)$$

$$\hat{U}(T, 0) = 1 - i \int_0^T \hat{\mathcal{H}}(t) dt - \int_0^T dt \int_0^t dt' \hat{\mathcal{H}}(t) \hat{\mathcal{H}}(t') + \dots \quad (8)$$

2 AVERAGE HAMILTONIAN THEORY

If the Hamiltonian is periodic, there is an advantage in evaluating $\hat{U}$ over a full period. Then the same $\hat{U}$ can be used to describe the long time development of the system as long as one is content with observing the system stroboscopically in synchrony with $\hat{\mathcal{H}}(t)$. We would like to express $\hat{U}$ in terms of an average Hamiltonian

$$\begin{aligned}\hat{U}(t_c, 0) &= \exp(-i\hat{\mathcal{H}}t_c) \\ \hat{U}(Nt_c, 0) &= \{\hat{U}(t_c, 0)\}^N = \exp\{-i\hat{\mathcal{H}}(Nt_c)\}\end{aligned}\quad (9)$$

However, while the operator $\hat{A} = -\hat{\mathcal{H}}t_c$ must be Hermitian, and the function $\exp(i\hat{A})$ of any Hermitian operator $\hat{A}$ is unitary, the truncated propagator of equation (8) is not unitary.

The Magnus expansion provides an escape from this problem: one tries from the beginning to find a unitary propagator in terms of a power series in $\lambda = -i$ as follows:

$$\hat{U}(T, 0) = \exp\{\lambda(\hat{a} + \lambda\hat{b} + \lambda^2\hat{c} + \dots)\} \quad (10)$$

One equates the coefficients of equal powers of λ in equations (8) and (10) [noting that equation (8) is such a series] to find the operators $\hat{a}$, $\hat{b}$, $\hat{c}$, $\dots$. The result, after putting the result in the form of equation (10), replacing λ by $-i$, and choosing $T = t_c$, is

$$\hat{\mathcal{H}} = \sum_n \hat{\mathcal{H}}^{(n)} \quad (11)$$

$$\hat{\mathcal{H}}^{(0)} = \frac{1}{t_c} \int_0^{t_c} \hat{\mathcal{H}}(t') dt' \quad (12)$$

$$\hat{\mathcal{H}}^{(1)} = \frac{-i}{2t_c} \int_0^{t_c} dt \int_0^t dt' [\hat{\mathcal{H}}(t), \hat{\mathcal{H}}(t')] \quad (13)$$

$$\begin{aligned}\hat{\mathcal{H}}^{(2)} &= \frac{-1}{6t_c} \int_0^{t_c} dt \int_0^t dt' \int_0^{t'} dt'' \{[\hat{\mathcal{H}}(t), [\hat{\mathcal{H}}(t'), \hat{\mathcal{H}}(t'')]] \\ &\quad + [\hat{\mathcal{H}}(t''), [\hat{\mathcal{H}}(t'), \hat{\mathcal{H}}(t)]]\}\end{aligned}\quad (14)$$

This series converges of course at a rate similar to equation (8), and is not useful unless the first few terms (in practice, usually the first and second) suffice.

3 REPRESENTATIONS AND FRAMES OF REFERENCE: TRUNCATION

The convergence of the Magnus series can be greatly influenced by one's choice of representation or frame of reference. As an example, begin with a laboratory frame Hamiltonian which includes static and radiofrequency fields as well as an internal Hamiltonian which might include chemical shifts, dipolar interactions, etc.:

$$\hat{\mathcal{H}}(t) = \omega_0 \hat{I}_z + 2\omega_1 \cos \omega t \hat{I}_x + \hat{\mathcal{H}}_{\text{int}} \quad (15)$$

$\hat{\mathcal{H}}(t)$ is periodic modulo $t_c = 2\pi/\omega$, and one might imagine applying equations (11)–(14) directly. But, if the rf frequency is near the Larmor frequency, $\hat{\mathcal{H}}t_c \approx \omega_0/\omega \approx 1$ and the perturbation theory will not converge. We take advantage of the elementary principle of quantum mechanics that no physical consequences are altered if all states $|a\rangle$ and all operators $\hat{Q}$ in a problem are transformed to a new representation by an arbitrary unitary operator $\hat{R}$:

$$|\tilde{a}\rangle = \hat{R}|a\rangle, \quad \hat{\tilde{Q}} = \hat{R}\hat{Q}\hat{R}^{-1} \quad (16)$$

In the new representation the time evolution is governed by an effective Hamiltonian:

$$\frac{\partial |a\rangle}{\partial t} = -i\hat{\mathcal{H}}_{\text{eff}}|a\rangle, \quad \hat{\mathcal{H}}_{\text{eff}} = \hat{R}\hat{\mathcal{H}}\hat{R}^{-1} - iU \frac{\partial \hat{U}^{-1}}{\partial t} \quad (17)$$

In the case of equation (15) the choice $\hat{R} = \exp(i\omega t \hat{I}_z)$ leads to

$$\begin{aligned}\hat{\mathcal{H}}_{\text{eff}} &= (\omega_0 - \omega)\hat{I}_z + \omega_1\{(1 + \cos 2\omega t)\hat{I}_x - \sin 2\omega t \hat{I}_y\} \\ &\quad + \hat{\mathcal{H}}_{\text{int}}(t)\end{aligned}\quad (18)$$

with $\hat{\mathcal{H}}_{\text{int}} \equiv \hat{R}\hat{\mathcal{H}}_{\text{int}}\hat{R}^{-1}$. In this interaction representation the size of the Hamiltonian is greatly reduced but t_c is the same as before, so the series in equation (11) converges very rapidly. (Because an operator of the form $\hat{R} = \exp(i\theta \hat{I}_z)$ generates a rotation in spin space through the angle θ , here about the z axis, the interaction representation can be associated with a *rotating frame of reference*. The fortunate circumstance that most of the transformations that are useful in magnetic resonance are of this form gives us this useful geometrical picture. A dominant quadrupolar coupling, for example, is not so kind.) The rotating frame also coincides with the laboratory frame at intervals of t_c , so that calculations made with reference to the rotating frame have relevance to experimental measurements. Indeed the requisite synchronization is often realized in practice by means of an rf phase detector referenced to ω .

To lowest order equation (18) gives just

$$\hat{\mathcal{H}}^{(0)} = (\omega_0 - \omega)\hat{I}_z + \omega_1 \hat{I}_x + \hat{\mathcal{H}}_{\text{int}}^{(0)} \quad (19)$$

whose first two terms describe the familiar effective field $\mathbf{B}_{\text{eff}}$ of magnitude $[(\omega_0 - \omega)^2 + \omega_1^2]^{1/2}$, inclined at the angle $\xi = \tan^{-1} [\omega_1/(\omega_0 - \omega)]$ to the main Zeeman field $\mathbf{B}_0$. To evaluate the third term, one must first write out the internal Hamiltonian explicitly. We take the example of the chemical shift:

$$\hat{\mathcal{H}}_{\text{int}} = \gamma \mathbf{B} \cdot \boldsymbol{\sigma} \cdot \hat{\mathbf{I}} \quad (20)$$

Since $\mathbf{B}_0$ is dominant and in the z direction, this simplifies to

$$\hat{\mathcal{H}}_{\text{int}} = -\omega_0(\sigma_{zx}\hat{I}_x + \sigma_{zy}\hat{I}_y + \sigma_{zz}\hat{I}_z) \quad (21)$$

Transforming to the rotating frame and averaging over one period t_c , we are left with the familiar result

$$\begin{aligned}\hat{\mathcal{H}}_{\text{int}} &= -\omega_0\{\sigma_{zz}\hat{I}_z + \sigma_{zx}(\hat{I}_x \cos \omega t - \hat{I}_y \sin \omega t) \\ &\quad + \sigma_{zy}(\hat{I}_y \cos \omega t + \hat{I}_x \sin \omega t)\}\end{aligned}\quad (22)$$

$$\hat{\mathcal{H}}_{\text{int}}^{(0)} = -\omega_0 \sigma_{zz} \hat{I}_z \quad (23)$$

At this point we remind the reader that σ_{zz} refers to a coordinate system fixed in the laboratory, not in the molecule containing the spin $\hat{\mathbf{I}}$. If $\mathbf{B}_0$ is in the direction (θ, φ) with respect to the principal axes (X, Y, Z) of the shielding tensor then

$$\sigma_{zz} = \sigma_{ZZ} \cos^2 \theta + \sigma_{XX} \sin^2 \theta \cos^2 \varphi + \sigma_{YY} \sin^2 \theta \sin^2 \varphi \quad (24)$$

If the molecule is tumbling rapidly and isotropically in a liquid, we must supplement the average already taken in spin space by an independent average over angles:

$$\bar{\sigma}_{zz} = \left(\frac{1}{3} \right) (\sigma_{XX} + \sigma_{YY} + \sigma_{ZZ}) = \frac{1}{3} \text{Tr } \sigma \quad (25)$$

Even though the motion of the molecule is not periodic, the average over angles is complete in a time much shorter than the sampling interval of the FID (see below).

So far we have looked only at the lowest order term in the Magnus expansion. The oscillations in the first and second terms of equation (19) give a correction

$$\hat{\mathcal{H}}_{\text{rf}}^{(1)} = \left(\frac{\omega_1}{2\omega} \right)^2 \hat{I}_z + \frac{\omega_1(\omega_0 - \omega)}{2\omega} \hat{I}_x \quad (26)$$

If the resonance frequency ω_{res} is defined as the frequency for which the coefficient of $\hat{I}_z$ vanishes then the first term of equation (26) represents the small Bloch–Siegert shift of the resonance condition away from its nominal frequency $\omega_{\text{res}} = \omega_0$ when the rf field is not of vanishing intensity.

Other internal Hamiltonians can be treated similarly. Consider the dipole–dipole interaction of a single pair of spins $\hat{\mathbf{I}}$ and $\hat{\mathbf{S}}$ having Larmor frequencies ω_{0I} and ω_{0S} which may or may not be different:

$$\hat{\mathcal{H}}_{\text{D}} = \frac{\gamma_I \gamma_S \hbar}{r^3} \left\{ \hat{\mathbf{I}} \cdot \hat{\mathbf{S}} - 3 \left(\hat{\mathbf{I}} \cdot \frac{\mathbf{r}}{r} \right) \left(\hat{\mathbf{S}} \cdot \frac{\mathbf{r}}{r} \right) \right\} \quad (27)$$

where $\mathbf{r}$ is a vector pointing from one spin to the other in space. By expanding the spin operators in Cartesian coordinates and $\mathbf{r}/r$ in spherical polar coordinates referred to $\mathbf{B}_0$, one finds, as Van Vleck² showed,

$$\hat{\mathcal{H}}_{\text{D}} = \gamma_I \gamma_S \hbar r^{-3} (\hat{A} + \hat{B} + \hat{C} + \hat{D} + \hat{E} + \hat{F}) \quad (28)$$

where

$$\left. \begin{aligned} \hat{A} &= -(3 \cos^2 \theta - 1) \hat{I}_z \hat{S}_z \\ \hat{B} &= \frac{1}{2} (3 \cos^2 \theta - 1) (\hat{I}_x \hat{S}_x + \hat{I}_y \hat{S}_y) \\ \hat{C} + \hat{D} &= -3 \sin \theta \cos \theta \{ (\hat{I}_z \hat{S}_x + \hat{I}_x \hat{S}_z) \cos \varphi + (\hat{I}_z \hat{S}_y + \hat{I}_y \hat{S}_z) \sin \varphi \} \\ \hat{E} + \hat{F} &= -\frac{3}{2} \sin^2 \theta \{ (\hat{I}_x \hat{S}_x - \hat{I}_y \hat{S}_y) \cos 2\varphi + (\hat{I}_x \hat{S}_y + \hat{I}_y \hat{S}_x) \sin 2\varphi \} \end{aligned} \right\} \quad (28a)$$

We can imagine a rotating frame transformation $\hat{S} = \exp(i\omega_{0I} \hat{I}_z + i\omega_{0S} \hat{S}_z)$ which makes various terms of $\hat{C}$ and

$\hat{D}$ oscillatory at frequencies ω_{0I} and ω_{0S} , terms $\hat{E}$ and $\hat{F}$ oscillatory at $\omega_{0I} + \omega_{0S}$, $\hat{B}$ oscillatory at $\omega_{0I} - \omega_{0S}$, and leaves $\hat{A}$ independent of time. Removing oscillatory terms gives a truncated Hamiltonian which depends on whether the spins are alike or different. In the latter case only term $\hat{A}$ survives. In the former, containing terms $\hat{A}$ and $\hat{B}$, the result is frequently written as

$$\begin{aligned} \hat{\mathcal{H}}_{\text{D},kl}^{(0)} = \hat{\mathcal{H}}_{\text{D},kl} &= \gamma_I \gamma_S \hbar r_{kl}^{-3} \left(\frac{3 \cos^2 \theta_{kl} - 1}{2} \right) \\ &\times (\hat{\mathbf{I}}_k \cdot \hat{\mathbf{I}}_l - 3 \hat{I}_{zk} \hat{I}_{zl}) \end{aligned} \quad (29)$$

Here the same symbol I is used for both spins to emphasize that they are of the same species, at the expense of the necessity of labels k and l .

Higher order corrections to the chemical shift and spin–spin Hamiltonians can be calculated in a manner similar to those that led to the Bloch–Siegert shift, but these are not of much practical importance.

4 APPLICATIONS

We have seen that the average Hamiltonian offers a convenient conceptual framework for approaching the truncation of Hamiltonians, and also a systematic way of evaluating corrections to the lowest order truncations. However, it also provides a guide for the synthesis of new and useful experiments. For example, one could have regarded the application of an intense external field as a deliberate measure for transforming the system Hamiltonian from one form, for example $\hat{\mathcal{H}}_{\text{D}}$, to another, $\hat{\mathcal{H}}_{\text{D}}'$. The requirement for this to be successful is that the external influence be *strong* compared with $\hat{\mathcal{H}}_{\text{int}}$ and that it generate an $\hat{\mathcal{H}}_{\text{int}}(t)$ which is *periodic* in a manner that can be synchronized with experimental observations. There are enough variables at the experimenter's disposal that average Hamiltonians can, to a surprising degree, be tailored to measure. In this section we illustrate this with several important examples.

4.1 Experiments with Steady rf Fields: Second Rotating Frame

4.1.1 Decoupling of Unlike Spins

Consider the situation in equation (20) when $\omega_{\text{eff}} = \gamma B_{\text{eff}}$ is large. We apply a second transformation $\hat{R}_2$ which removes $\mathbf{B}_1$ in the same way that $\hat{R}$ removed $\mathbf{B}_0$ (or most of it). It is convenient to do this in two stages: $\hat{R}_2 = \hat{S} \hat{T}$, with $\hat{T} = \exp(i\xi \hat{I}_y)$. This creates a new z axis parallel to $\mathbf{B}_{\text{eff}}$. The second transformation $\hat{S} = \exp(i\omega_{\text{eff}} t \hat{I}_z)$ then induces the *second tilted rotating (STR) frame*, in which

$$\hat{\mathcal{H}}_{\text{eff}}^{(\text{STR})}(t) = \hat{S} \hat{T} \hat{\mathcal{H}}_{\text{int}}^{(0)} \hat{T}^{-1} \hat{S}^{-1} \quad (30)$$

Take as an example $\hat{\mathcal{H}}_{\text{int}}^{(0)} = K \hat{I}_z \hat{S}_z$, the coupling between two unlike spins truncated as described above. (In the case of

dipolar coupling $K = -\gamma_I \gamma_S \hbar r^{-3} (3 \cos^2 \theta - 1)$. For scalar coupling in liquids, expressible as $J \hat{\mathbf{I}} \cdot \hat{\mathbf{S}}$ in the laboratory, one gets the same form with $K = J$.) We imagine that the rf field of equation (16) and equation (20) is applied near the I -spin resonance, so that the transformations T and S involve only I -spin variables as indicated. (It is easily verified that the final results are unchanged if we apply an arbitrary transformation to the S -spin operators.) The result of the two transformations is

$$\hat{\mathcal{H}}_{\text{eff}}^{(\text{STR})}(t) = K \hat{S}_z \{ \hat{I}_z \cos \xi - (\hat{I}_x \cos \omega_{\text{eff}} t - \hat{I}_y \sin \omega_{\text{eff}} t) \sin \xi \} \quad (31)$$

and the average Hamiltonian is

$$\hat{\mathcal{H}}^{(0, \text{STR})} = K_{\text{eff}} \hat{I}_z \hat{S}_z, \quad K_{\text{eff}} = K \cos \xi = K \left(\frac{\omega_0 - \omega}{\omega_e} \right) \quad (32)$$

The coupling constant has been effectively reduced: for irradiation exactly at resonance it vanishes altogether.

Note that $\hat{\mathcal{H}}_{\text{eff}}(t)$ is periodic modulo $t_c = 2\pi/\omega_e$, which depends on the irradiation conditions and is not conveniently synchronized with data acquisition. The average Hamiltonian concept is therefore not well suited to this experiment: in fact equation (32) is correct for certain values of ω_e , but for all other values K_{eff} is smaller than predicted.

4.1.2 Recoupling of Unlike Spins: The Hartmann–Hahn Effect

We have just shown that applying a strong rf field at the Larmor frequency of one of two species of unlike coupled spins removes their coupling. We now show that simultaneous irradiation at both Larmor frequencies not only restores the coupling, but makes the spins appear to be of the same species, in the sense that they can undergo mutual spin flips. For the first time we allow explicitly for the presence of many spins of both types:

$$\hat{\mathcal{H}}'_D = \hat{\mathcal{H}}_{II} + \hat{\mathcal{H}}_{SS} + \hat{\mathcal{H}}_{IS} \quad (33a)$$

where

$$\hat{\mathcal{H}}_{IS} = -\gamma_I \gamma_S \hbar \sum_k \sum_p r_{kp}^{-3} (3 \cos^2 \theta_{kp} - 1) \hat{I}_{zk} \hat{S}_{zp} \quad (33b)$$

is a sum over all pairs of unlike spins, and $\hat{\mathcal{H}}_{II}$ and $\hat{\mathcal{H}}_{SS}$ are sums of terms of the form of equation (26). The transformation to be applied is now

$$\hat{S} \hat{T} = \exp\{i(\omega_{\text{eff}, I} \hat{I}_z + \omega_{\text{eff}, S} \hat{S}_z)t\} \exp\{i(\xi_I \hat{I}_y + \xi_S \hat{S}_y)\} \quad (34)$$

where $\hat{I}_z = \sum \hat{I}_{zk}$, etc. As before, all Zeeman terms are removed but attach their respective oscillations to the I and S spin operators in equation (33), etc., resulting in oscillatory time-dependences at $\omega_{\text{eff}, I}$, $\omega_{\text{eff}, S}$ and their sum and difference, as well as a time-independent part. We average first over all

oscillating terms except the one at the lowest frequency $\Delta = \omega_{\text{eff}, I} - \omega_{\text{eff}, S}$:

$$\hat{\mathcal{H}}^{(0, \text{STR})} = \hat{\mathcal{H}}_{II} P_2(\cos \xi_I) + \hat{\mathcal{H}}_{SS} P_2(\cos \xi_S) + \hat{\mathcal{H}}_{IS} \cos \xi_I \cos \xi_S + \hat{\mathcal{H}}_{\text{ff}}(t) \quad (35)$$

$$\begin{aligned} \hat{\mathcal{H}}_{\text{eff}}(t) = & \frac{1}{2} \exp\{-\frac{1}{2}i \Delta t (\hat{I}_z - \hat{S}_z)\} \\ & \times \sum_k \sum_{l \neq k} K'_{kl} (\hat{I}_{+k} \hat{I}_{-l} + \hat{I}_{-k} \hat{I}_{+l}) \exp\{\frac{1}{2}i \Delta t (\hat{I}_z - \hat{S}_z)\} \end{aligned} \quad (36)$$

$$K'_{kl} = K_{kl} \sin \xi_I \sin \xi_S \quad (37)$$

The best known application of this result is the irradiation of both species at resonance and adjustment of Δ to zero (Hartmann–Hahn condition.³ The now static term $\hat{\mathcal{H}}_{\text{ff}}$ leads to mutual flips of interacting I and S spins, which could not occur under the normal truncated spin–spin Hamiltonian [equation (33)].

The actual behavior in many-spin systems is complicated by the terms in $\hat{\mathcal{H}}_{II}$ and $\hat{\mathcal{H}}_{SS}$ (although most applications are to systems in which the S spins are very dilute and $\hat{\mathcal{H}}_{SS}$ can be neglected). The Hartmann–Hahn effect in concert with IS decoupling [cf. equation (33)] forms the basis of a widely used technique for resolved dilute spin spectroscopy in solids.⁴

4.2 Pulsed RF Fields: The Toggling Frame

Consider a solid having only a single spin species, I . Everything drops out of equation (35) except the first term, which vanishes as well if the irradiation is performed at the magic angle in the rotating frame, $\xi_m = \tan^{-1} \sqrt{2}$. Such an experiment evidently accomplishes decoupling of like spins. Early experimenters who recognized this fact⁵ did not notice the contrast of this behavior with the effect on chemical shifts [equation (23)] for which

$$\hat{\mathcal{H}}^{(0, \text{STR})} = -\omega_0 \sum_k \alpha_{zzk} (\hat{I}_{zk} \cos \xi_I + \hat{I}_{yk} \sin \xi_I) \quad (38)$$

does not vanish. Returning equation (38) to the z axis by reversing the transformation $\hat{T}$, we recover just equation (23) with a scale factor of $1/\sqrt{3}$. That is, chemical shifts are in principle extractable from a background of static dipole–dipole broadening in solids.

At this point we need to remember the higher order corrections to the Magnus series, which we have been ignoring for the most part. In experiments on rf irradiation of solids, practical rf fields are not sufficient to dominate the internal Hamiltonian to the extent that $\mathbf{B}_0$ does in the laboratory frame, and $\hat{\mathcal{H}}_{II}^{(1)}$ can often be comparable in size to equation (35). To remove $\hat{\mathcal{H}}_{II}^{(1)}$, we need further degrees of freedom in the design

of rf irradiation, in particular modulation of the amplitude and phase of the rf carrier. The analysis is especially simple if we idealize the rf envelope as a train of Δ -functions. Each such pulse contains a particular carrier phase, which we choose for simplicity from the set 0° , 90° , 180° , and 270° , which lead to instantaneous rotations about the x , y , $-x$, and $-y$ axes of the rotating frame. We imagine repetition of a short sequence which has cyclic behavior, so that stroboscopic observations made once per cycle have relevance to the laboratory frame of reference.

The propagator $\hat{U}$ for a sequence of n pulses in the rotating frame can be abbreviated as

$$\hat{U} = [\hat{\mathcal{H}}, \tau_n] \hat{P}_n [\hat{\mathcal{H}}, \tau_{n-1}] \cdots [\hat{\mathcal{H}}, \tau_1] \hat{P}_1 \quad (39)$$

where $[\hat{\mathcal{H}}, \tau_k]$ represents a free development of the spin system under its internal Hamiltonian $\hat{\mathcal{H}}$ during the interval τ_k and $\hat{P}_k$ represents the rotation produced by the pulse about some axis $\mu = x, y, \dots$, during which the internal Hamiltonian is neglected:

$$[\hat{\mathcal{H}}, \tau_k] = \exp(-i\hat{\mathcal{H}}\tau_k), \quad \hat{P}_k = \exp(-i\theta_k \hat{I}_\mu) \quad (40)$$

By convention, the observations of the system are made at the end (left) of the sequence as written. We wish to find a transformation which removes the rf pulses, by analogy to the second rotating frame transformation which removed a steady rf field. This can be done by judicious insertion of identity transformations $\hat{P}_m \hat{P}_m^{-1}$ in such a way as to accumulate all the $\hat{P}$ terms in $\hat{U}$ at the end (left) and to replace the free interpulse developments under the normal Hamiltonian $\hat{\mathcal{H}}$ by a sequence of developments under transformed Hamiltonians $\hat{\mathcal{H}}_k$:

$$\hat{U} = \hat{P}_n [\hat{\mathcal{H}}_n, \tau_n] [\hat{\mathcal{H}}_{n-1}, \tau_{n-1}] \cdots [\hat{\mathcal{H}}_1, \tau_1] \quad (41)$$

where

$$\hat{\mathcal{H}}_k = \hat{P}_k^{-1} \hat{\mathcal{H}} \hat{P}_k, \quad \hat{P}_k = \hat{P}_k \hat{P}_{k-1} \cdots \hat{P}_1 \quad (42)$$

The cyclic property makes $\hat{P}_n = 1$.

4.2.1 Removal of Inhomogeneous Shifts: Spin Echoes

As an example consider the case of inhomogeneous shifts $\hat{\mathcal{H}}_\delta$, arising from chemical shift as in equation (23), from an inhomogeneous Zeeman field or from coupling to unlike spins. We apply a sequence of equally spaced 180° pulses alternately along the y and $-y$ axes of the rotating frame: since these pulses are inverses of one another,

$$\begin{aligned} \hat{U} &= 1 \cdot [\hat{\mathcal{H}}_2, \tau] [\hat{\mathcal{H}}_1, \tau], \quad \hat{\mathcal{H}}_2 = \hat{\mathcal{H}}_\delta, \\ \hat{\mathcal{H}}_1 &= \hat{P}_1 \hat{\mathcal{H}}_\delta \hat{P}_1^{-1} = -\hat{\mathcal{H}}_\delta \end{aligned} \quad (43)$$

and $\hat{\mathcal{H}}$ switches sign. Note the following.

1. $\hat{\mathcal{H}}^{(0)} = 0$: the system returns to its original quantum state at intervals $t_c = 2\tau$. If a nonzero magnetization was present at $t = 0$, it returns at the end of each cycle in the form of a spin echo.

2. The reversed sign of the $\hat{\mathcal{H}}_1$ in the toggling frame is equivalent to a reversal in the direction of time.
3. While in this example the system was observed just before a pulse, the results are easily seen to be independent of the observing phase.
4. Since $[\hat{\mathcal{H}}_1, \hat{\mathcal{H}}_2] = 0$, all higher orders $\hat{\mathcal{H}}^{(n)0}$ vanish: the result is correct even if $\delta\tau \gg 1$.

4.2.2 Decoupling of Like Spins: Multiple Pulse Sequences

The last two of these results are special to the inhomogeneous Hamiltonian. A contrary example is provided by the WAHUA sequence—the one for which the average Hamiltonian theory was developed in the first place.⁶ The cycle consists of four unequally spaced 90° pulses along the x , y , $-x$, and $-y$ directions in the rotating frame:

$$\hat{U} = [\hat{\mathcal{H}}, \tau] \hat{P}_{-y} [\hat{\mathcal{H}}, 2\tau] \hat{P}_y [\hat{\mathcal{H}}, \tau] \hat{P}_{-x} [\hat{\mathcal{H}}, 2\tau] \hat{P}_x \quad (44)$$

Equation (42) can be written as

$$\hat{U} = 1 \cdot [\hat{\mathcal{H}}_Z, \tau] [\hat{\mathcal{H}}_X, 2\tau] [\hat{\mathcal{H}}_Z, \tau] [\hat{\mathcal{H}}_Y, 2\tau] \quad (45)$$

where $\hat{\mathcal{H}}_Z$ is the normal rotating frame Hamiltonian, e.g. equation (23) or equation (29), the subscript being a reminder that z component operators $\hat{I}_{zk}$ appear explicitly. The terms $\hat{\mathcal{H}}_x$ and $\hat{\mathcal{H}}_y$ are the same except that these operators are replaced by $\hat{I}_{xk}$ or $\hat{I}_{yk}$, respectively. Now it is easy to see that the average Hamiltonian for inhomogeneous shifts is

$$\hat{\mathcal{H}}_{\delta,k}^{(0)} = \frac{1}{3} \delta_k (\hat{I}_{xk} + \hat{I}_{yk} + \hat{I}_{zk}) \quad (46)$$

and that for like-spin dipolar interactions is

$$\begin{aligned} \hat{\mathcal{H}}_{D,kl}^{(0)} &= \frac{\gamma^2 \hbar}{r_{kl}^3} \left(\frac{3 \cos^2 \theta_{kl} - 1}{2} \right) \\ &\times \{ \hat{\mathbf{I}}_k \cdot \hat{\mathbf{I}}_l - (\hat{I}_{xk} \hat{I}_{xl} + \hat{I}_{yk} \hat{I}_{yl} + \hat{I}_{zk} \hat{I}_{zl}) \} = 0 \end{aligned} \quad (47)$$

These results are the same (modulo a rotation through 45° about the z axis) as for steady rf irradiation at the magic angle mentioned at the beginning of this section. The difference is that in the pulsed case it is possible to make the next order in the dipolar average Hamiltonian vanish. However, to do so, the observation point in the cycle must be properly chosen. If the cycle is phased as:

$$\hat{U} = [\hat{\mathcal{H}}, \tau] \hat{P}_x [\hat{\mathcal{H}}, \tau] \hat{P}_{-y} [\hat{\mathcal{H}}, 2\tau] \hat{P}_y [\hat{\mathcal{H}}, \tau] \hat{P}_{-x} [\hat{\mathcal{H}}, \tau] \quad (48)$$

the development in the toggling frame is

$$\hat{U} = 1 \cdot [\hat{\mathcal{H}}_Z, \tau] [\hat{\mathcal{H}}_Y, \tau] [\hat{\mathcal{H}}_X, 2\tau] [\hat{\mathcal{H}}_Y, \tau] [\hat{\mathcal{H}}_Z, \tau] \quad (49)$$

The symmetry about the midpoint of the cycle causes the integral in equation (13) to vanish. [In fact, experimental constraints dictate the phasing in equation (50) in any case.]

4.3 Mechanical Rotation

Most of the averaging discussed so far has been over precessional motions in spin space. However, spin Hamiltonians such as that in equation (29) can also be made time-dependent by physical motions in coordinate space. These can be random motions of individual molecules or coherent motions of the entire sample. In the latter category, we consider the bodily rotation of a sample with truncated dipolar interactions, either like or unlike, at frequency ω_r about an axis making an angle χ with $\mathbf{B}_0$. By expressing θ in terms of χ and $\omega_r t$, it is easily found that the average of $\hat{\mathcal{H}}'_D$ over the time $t_{cr} = 2\pi/\omega_r$ is

$$\langle \hat{\mathcal{H}}'_D \rangle_{Av} = \frac{1}{2}(3 \cos^2 \chi - 1) \hat{\mathcal{H}}'_D \quad (50)$$

which vanishes for ‘magic angle’ rotation, $\chi = \tan^{-1} \sqrt{2}$. The same is true for other interactions, such as chemical shielding, which transform as second-rank tensors under spatial rotations. Tensors of higher rank possess more than one ‘magic angle’ (i.e. nodal cone) and cannot be averaged by uniaxial rotation. Second- and fourth-rank tensors can both be averaged by sequential or simultaneous rotations about two axes;⁷ this has special relevance to quadrupolar interactions, which to first order in e^2qQ/ω_0 transform as second-rank tensors but in second order have a fourth-rank part.

Magic angle rotation is more effective than one might expect for inhomogeneous interactions⁸ such as chemical shielding and quadrupolar coupling, for which the Hamiltonian is a sum of single-spin terms. There the question of commutation of $\hat{\mathcal{H}}(t)$ at different times does not arise, since each spin develops independently and its part of the Hamiltonian is a fixed spin operator multiplied by a time-dependent scalar coefficient. Then the lowest order average Hamiltonian $\hat{\mathcal{H}}^{(0)}$ is exact. Important advantage of this is taken in the CP MAS technique⁹ for extracting sharp chemical shift spectra from dilute species in solids. (Homogeneous interactions, dipolar in particular, do not have this property: the interaction between spins j and k does not commute with the interaction between k and l at different orientations of the triplet unless the three spins are collinear.)

5 ADDITIONAL TOPICS

5.1 Asynchronism

We have emphasized the importance of the periodicity of effective Hamiltonians $\hat{\mathcal{H}}(t)$ and synchronism of such periods with experimental measurement. These requirements can be relaxed to a degree if the timescale over which $\hat{\mathcal{H}}(t)$ varies is much shorter than the interval t_s between measurements. First consider the use of a truncated (rotating frame) average Hamiltonian to describe a typical FID. In principle, the

truncated Hamiltonian describes the system only over full Larmor periods. If t_s is not an integer multiple of t_c , the last fractional Larmor period should be associated with a different average Hamiltonian. Clearly, since several thousand Larmor periods $t_c = 2\pi/\omega_0$ occur between samples, the time-weighted average of these two Hamiltonians is essentially the same as the usual truncated Hamiltonian and the correction can be ignored.

The same considerations apply in evaluating the average Hamiltonian in a second rotating frame or toggling frame, where the cycle time associated with the second average is long compared to laboratory Zeeman periods. Here, however, it is essential that data acquisition be synchronized with the slower cycle time.

A similar argument allows us to deal with averaging due to random molecular motion, at least in the limit of extreme narrowing. The average of the Hamiltonian over a time T converges to a constant value as T becomes long compared with the correlation time τ_c . If t_s is long compared with τ_c , this average can be used. However, the theory provides no guidance to behavior in the transition from slow to fast motion.

5.2 Multiple Time Dependences: Interference

Some two- (and higher) dimensional NMR experiments depend on applying different external perturbations, thereby generating different average Hamiltonians during different epochs of the same experiment. An example is separated local field (SLF) NMR,¹⁰ in which chemical shifts and dipolar couplings are separated into two dimensions.

A different situation arises when two or more different time dependences are present simultaneously. Sometimes these can be turned to practical advantage, as in the recovery of chemical shift anisotropies from MAS experiments by applying pulses synchronous with the sample rotation.¹¹ Perhaps more commonly they are a nuisance: the addition of MAS to multiple pulse experiments (CRAMPS)¹² in order to remove chemical shift anisotropies inevitably compromises the effectiveness of the multiple pulse train in reducing dipolar broadening. Random molecular motions which are too slow to affect conventional NMR spectra may show themselves when sample spinning with $\omega_r \approx \tau_c^{-1}$ or decoupling with $\gamma B_1 \approx \tau_c^{-1}$ are present.

5.3 Thermodynamics

A conservative system of many interacting particles, such as an assembly of spins with dipolar interactions as in equation (30), is expected to approach thermodynamic equilibrium with a density matrix

$$\sigma_{eq} = \frac{\exp(-\hat{\mathcal{H}}/k_B T)}{\text{Tr}\{\exp(-\hat{\mathcal{H}}/k_B T)\}} \quad (51)$$

The essence of the average Hamiltonian concept is the treatment of an explicitly time-dependent system as if it were conservative with Hamiltonian $\bar{\mathcal{H}}$. The application of thermodynamics to such systems has been questioned¹³ and extensively discussed.¹⁴ Thermodynamics is a practical

science: it does not require that the system remain in the equilibrium expressed in equation (51) forever, but only that it reaches that condition and remains long enough to permit measurements. Therefore one is free to speak of spin temperatures in the laboratory frame despite the existence of (slow) spin–lattice relaxation. Redfield’s extension of the spin-temperature concept to the rotating frame,¹⁵ even in the presence of rf irradiation as in equation (18) and equation (19), explained many previously mystifying observations. One can understand these successes by observing that the frequencies contained in the time-dependent parts of $\hat{\mathcal{H}}(t)$, for example phonons or the terms dropped in going from equation (18) to equation (19) or from equation (28) to equation (29), are far from resonant, with eigenvalue differences belonging to the static part of $\hat{\mathcal{H}}(t)$. Of course, a second averaging done with respect to the STR frame or toggling frame is more questionable, but in many cases satisfies the requirements of equation (51) adequately. In any case, the principal applications of the average Hamiltonian are to spectroscopy.

1 INTRODUCTION

The development of cross polarization (CP) techniques, allowing the transfer of magnetization from a system of spins I with high abundance (e.g. ^1H , ^{19}F , and ^{31}P) to a system of spins S with low natural abundance (e.g. ^{13}C and ^{15}N) was a major step to *enhance the sensitivity* of these rare nuclei in solid state NMR.^{1–3} As the sensitivity thresholds for rare nuclear spins have been lowered, NMR has become available for extensive studies of solid materials.

A second problem peculiar to solid state NMR originates from the fact that, in solids, molecules or molecular groups are generally not subject to fast isotropic motions as they are in liquids. Consequently, NMR applied to solid samples, e.g. polycrystalline or amorphous materials, is characterized by spatially anisotropic spin interactions. The dominating interactions for spin- $\frac{1}{2}$ nuclei in solids are the direct dipole–dipole coupling between spins, and the magnetic shielding due to the electronic environment of a given nucleus, causing the chemical shift of resonance lines. The resulting spectra of polycrystalline or amorphous samples typically reveal broad lineshapes reflecting these anisotropic interactions. It was a major technical goal in NMR to invent techniques which play, at least in part, a role analogous to that of thermal motion in liquids, i.e. to average out or reduce the anisotropic contribution of the spin interactions. This averaging can take place either in spin space or in ordinary coordinate space,^{4,5} depending on the interaction. To remove homonuclear dipolar couplings, averaging in spin space requires the application of multiple pulse sequences (see **CRAMPS**). In order to eliminate broadening of resonance lines of rare S spins due to heteronuclear dipolar interactions with abundant I spins, rf irradiation near the Larmor frequency of I spins can be applied (heteronuclear high power decoupling³). The removal of line broadening originating from the chemical shift anisotropy (CSA) can be accomplished by averaging performed in coordinate space, i.e. by rotating the sample around a spatially fixed axis inclined by a specific angle θ_m , called the ‘magic angle’, relative to the

direction of the external field B_0 . Magic angle spinning (MAS) and some descendent techniques are nowadays well established and routinely included in high-resolution solid state NMR studies, allowing the identification of chemical environments by the isotropic chemical shift.

Fast sample rotation also affects homo- and heteronuclear dipole–dipole couplings.^{6,7} Because these interactions provide the physical basis on which polarization transfer between different spin systems occurs, they are here considered first in some detail (see Sections 2 and 3). Following these considerations, the influence of sample spinning on the CP process will be discussed (Sections 4 and 5). Because sample spinning may impose dramatic effects on the CP process, effects which are undesirable from an experimental point of view, the possibilities of circumventing some of these difficulties are reviewed in Section 6. Since the majority of applications are based on the spin lock, cross polarization technique, proposed by Hartmann and Hahn,¹ and Pines, Gibby, and Waugh,² the present article is concerned with this method.²⁸ For details of other techniques, such as adiabatic demagnetization in the rotating frame^{1,3} and the nuclear solid effect,^{8,12} the reader is referred to the literature (see also **Cross Polarization in Solids**).

2 MAGNETIZATION TRANSFER IN THE RADIOFREQUENCY ROTATING FRAME

Figure 1 shows the basic pulse sequence used in CP experiments.^{2,3} Initially, a 90° ($\pi/2$) pulse is applied at the resonance frequency ω_{0I} of the abundant I spins with magnetogyric ratio γ_I , creating transverse magnetization. In the subsequent time interval, denoted by τ_{CP} , the rf field (strength in angular frequency units $\Omega_{II} = \gamma_I B_{1I}$) is applied parallel to the transverse I -spin magnetization, thus locking the magnetization in the direction of the B_{1I} rf field. Simultaneously, rf irradiation (strength $\Omega_{IS} = \gamma_S B_{1S}$) occurs at the resonance frequency ω_{0S} for the rare S spins with magnetogyric ratio γ_S , the initial transverse magnetization of which is zero. If the Hartmann–Hahn condition¹

$$\gamma_I B_{1I} = \gamma_S B_{1S} \quad (1)$$

Figure 1 Pulse sequence for standard cross polarization. Radiofrequency irradiation occurs at the Larmor frequencies ω_{0I} and ω_{0S} for I and S spins simultaneously

for the rf field strengths is satisfied, transfer of magnetization from the I -spin system to the S -spin system can take place during the cross polarization mixing time τ_{CP} , resulting in a build-up of transverse S -spin magnetization, which can be observed after switching off the rf field in the S -spin channel. During this acquisition period, the rf irradiation in the I -spin channel may continue to provide decoupling of the I - S dipolar interaction.³

The elementary process for cross polarization involves transitions of dipolar-coupled I and S spins, frequently called flip-flop transitions or mutual spin flips, because one spin is changing its state from a higher to a lower energy, while simultaneously a neighboring spin moves from a state with lower to a state with higher energy. If a solid, containing systems of spins I and S with different magnetogyric ratios γ_I and γ_S , is subjected only to the external magnetic field B_0 , then the energy levels for both systems are given by the Zeeman interaction in the laboratory frame. The splitting of energy levels (in angular frequency units) is different for I and S spins, and is equal to their respective Larmor frequencies ω_{0I} and ω_{0S} [Figure 2(a)]. Under these circumstances flip-flop transitions involving I - S spin pairs possess a vanishingly small probability rate, because the (virtual) photon which would be emitted during an I -spin transition could not be absorbed by an S -spin transition between Zeeman energy levels. This situation changes if rf fields are present for both spin systems [Figure 2(b)]. The total Hamiltonian of the two spin systems in the laboratory frame of reference becomes oscillatory time dependent due to the presence of rf fields. It is convenient to choose a frame of reference which is rotating with the applied rf fields (doubly rotating frame), generally known in quantum mechanics as the transformation from the Heisenberg operator representation to the interaction representation.⁹ In this frame the time dependence originating from the rf fields (frequencies ω_k , $k = I$ or S) vanishes¹⁰ for $\omega_k = \omega_{0k}$ (on-resonance). Identifying the new z axis with the direction of the rf field vectors B_{1I} and B_{1S} , the total spin Hamiltonian in this tilted rotating frame (TRF)^{3,13} with spin components $\hat{I}_{zk}$, $\hat{I}_{xk}$ for the spins I_k , $\hat{I}_z = \sum_k \hat{I}_{zk}$ and the spin

components $\hat{S}_z$, $\hat{S}_x$ for a single S spin is:

$$\begin{aligned}\hat{\mathcal{H}} &= \hat{\mathcal{H}}_I + \hat{\mathcal{H}}_S + \hat{\mathcal{H}}_{IS} \\ \hat{\mathcal{H}}_I &= -\Omega_{1I}\hat{I}_z + \hat{\mathcal{H}}_{II} \quad \hat{\mathcal{H}}_S = -\Omega_{1S}\hat{S}_z \\ \hat{\mathcal{H}}_{IS} &= 2 \sum_k D_k \hat{I}_{xk} \hat{S}_x\end{aligned}\quad (2)$$

where it has been assumed that both rf fields are in resonance with the I and S spins, respectively. $\hat{\mathcal{H}}_I$ denotes the Hamiltonian for the I -spin system, whereas $\hat{\mathcal{H}}_{II}$ and $\hat{\mathcal{H}}_{IS}$ are the I - I homonuclear and I - S heteronuclear dipolar Hamiltonians. The homonuclear dipolar couplings among S spins can be neglected, due to the low abundance of S spins. D_k denotes the dipolar coupling strength between spin S and spin I_k . The above Hamiltonian includes the two terms $\Omega_{1I}\hat{I}_z$ and $\Omega_{1S}\hat{S}_z$, which represent the Zeeman interaction in the TRF for I and S spins, respectively. The corresponding splitting of Zeeman energy levels in the TRF, therefore, is given by Ω_{1I} and Ω_{1S} , which are experimental parameters. Satisfying the Hartmann-Hahn matching condition $\Omega_{1I} = \Omega_{1S}$ [equation (1)] provides equal TRF-Zeeman splittings for both spin systems, such that an energy transfer can take place between I and S spins [Figure 2(b)].

3 CROSS POLARIZATION AND DIPOLAR COUPLING

It is instructive to consider first a simple system, consisting of an isolated dipolar-coupled I - S spin pair, providing some basic concepts necessary to show the impact which MAS has on cross polarization. The energy levels of the spin system, i.e. the possible total energies of both spins, are shown in Figure 3(a). $|++\rangle$, $|+-\rangle$, etc., denote product TRF-Zeeman spin-state vectors $|m_I, m_S\rangle$ (with magnetic quantum numbers $m_{I,S} = +\frac{1}{2}$ for the z -spin component parallel, and $m_{I,S} = -\frac{1}{2}$ for the z -spin component antiparallel to the rotating rf field). If dipolar couplings are not present and $\Delta\Omega = \Omega_{1I} - \Omega_{1S} = 0$, then Zeeman state vectors are eigenvectors of the TRF Hamiltonian. The two states with antiparallel spin orientations are degenerate (i.e. having the same energy). $\Delta\Omega \neq 0$ removes this degeneracy, the eigenstates are now $|2\rangle$ and $|3\rangle$. For small $\Delta\Omega$ the magnetic quantum numbers m_I and m_S are still ‘good’ quantum numbers. The presence of $\hat{\mathcal{H}}_{IS}$ leads to transitions between Zeeman states or, in general, between $|2\rangle$ and $|3\rangle$, and $|1\rangle$ and $|4\rangle$. In Figure 3(a) the probabilities of these transitions are labeled W_0 and W_2 . The same holds for $\Delta\Omega = 0$ for the Zeeman states $|++\rangle$, $|+-\rangle$, $| - + \rangle$, and $| -- \rangle$. The energy levels in the TRF, including the dipolar Hamiltonian $\hat{\mathcal{H}}_{IS}$ and $\Delta\Omega$ being non-zero, can be obtained from the Hamiltonian $\hat{\mathcal{H}}$ in equation (2) (with $\hat{\mathcal{H}}_{II} = 0$) by using a matrix representation with the Zeeman state vectors, and solving the eigenvalue problem for $\hat{\mathcal{H}}$. The transition probabilities W_0 and W_2 are then given as the square modulus of the corresponding matrix elements of the time evolution operator⁹ $\hat{U}(t) = \exp(-i\hat{\mathcal{H}}t)$. If the sum of the two rf fields, $\Sigma = \Omega_{1I} + \Omega_{1S}$, is large compared to their difference $\Delta\Omega = \Omega_{1I} - \Omega_{1S}$, and to the dipolar coupling strength D between I and

Figure 2 Energy levels of I and S spins (a) in the laboratory frame and (b) in the rf rotating frame

Figure 3 (a) Energy levels of an I - S two-spin system in the tilted rotating frame for matching ($\delta\Omega = 0$) and mismatching ($\delta\Omega \neq 0$) the Hartmann-Hahn condition; (b) Hartmann-Hahn matching curve for a nonrotating solid

S spins, and if, in addition, the quantity $\Delta\Omega$ (referred to in the following as Hartmann-Hahn mismatch) is small compared to D , then the flip-flop transition probability W_0 dominates. W_0 depends on the coupling strength D , and is much larger than W_2 :

$$W_0 \propto \frac{D^2}{D^2 + \Delta\Omega^2} \approx 1, \quad W_2 \propto \frac{D^2}{D^2 + \Sigma^2} \ll 1 \quad (3)$$

for D , $\Delta\Omega \ll \Sigma$, and $\Delta\Omega \ll D$. In general, I - I dipolar couplings are present in the solid, giving rise to a broadening of the I -spin levels.^{11,12} With increasing mismatch $\Delta\Omega$, the two energy levels for the states $|2\rangle$ and $|3\rangle$ of the I - S spin system shift relative to each other [Figure 3(a)], and for $\Delta\Omega > D$ [equation (3)] and $\delta\Omega$ larger than the I - I dipole couplings, the transition probability W_0 decreases significantly.

An entirely isolated I - S spin system would periodically exchange magnetization between I and S spin. The presence of many spins interacting with each other introduces the statistical, or thermodynamic, aspect^{3,13,14} into cross polarization.

Under standard CP conditions (Figure 1) the initial I -spin magnetization is transferred irreversibly to the S -spin system. However, the behavior of the elementary flip-flop transition allows one to understand, at least qualitatively, the efficiency of CP under mismatch conditions ($|\Delta\Omega| \neq 0$), as illustrated in Figure 3(b). The polarization transfer is most efficient for $\Delta\Omega = 0$. Increasing mismatch leads to a gradual decrease of S -spin magnetization as long as the levels of the spin states $|2\rangle$ and $|3\rangle$ still overlap, originating from their finite width due to I - I dipolar couplings. CP becomes completely inefficient if the mismatch becomes larger than the I - I dipolar coupling strengths. The plot of S -spin magnetization obtained by CP versus mismatch $\Delta\Omega$ is called the Hartmann-Hahn or CP-matching curve, and is drawn schematically in Figure 3(b). As will be shown below, the CP-matching curve, as an indicator of efficiency for I - S magnetization transfer, is of utmost importance when combining CP and MAS.

The result that magnetization transfer conserving the total spin energy occurs predominantly for small mismatch $\Delta\Omega$ can be expressed by the selection rules

$$\Delta m_I + \Delta m_S = 0, \quad |\Delta\Omega| \leq D_{IS}, D_{II} \quad (4)$$

i.e. CP takes place via flip-flop transitions (total change of the magnetic quantum numbers m_I and m_S is zero). The second condition in equation (4) includes the broadening of TRF-Zeeman levels, leading to a CP-matching curve of finite width.

4 DIPOLAR COUPLINGS IN ROTATING SOLIDS

The dipolar coupling strengths D_{jk} between two spins j and k depend on their mutual distance r_{jk} and on the orientational angle ϑ_{jk} of the internuclear vector $\mathbf{r}_{jk}$ relative to the static field $\mathbf{B}_0$ (see also *Internal Spin Interactions and Rotations in Solids*):

$$D_{jk} = \frac{\mu_0 \gamma_j \gamma_k \hbar^2}{4\pi r_{jk}^3} \frac{1}{2} (3 \cos^2 \vartheta_{jk} - 1) \quad (5)$$

Spinning of the sample around an axis tilted by the angle θ_m relative to $\mathbf{B}_0$ leads to a periodic time dependence of the angle ϑ_{jk} with the frequency ω_r of rotation as shown in Figure 4. The time-dependent term $\cos \vartheta_{jk}(t)$ can be expressed as a function of the angles θ_m , θ_{jk} and $\omega_r t$, and the angle-dependent part of D_{jk} then reads

$$(3 \cos^2 \vartheta_{jk}(t) - 1) = \frac{1}{2} (3 \cos^2 \theta_m - 1) (3 \cos^2 \theta_{jk} - 1) + \frac{3}{2} \sin 2\theta_m \sin 2\theta_{jk} \cos(\omega_r t) + \frac{3}{2} \sin^2 \theta_m \sin^2 \theta_{jk} \cos(2\omega_r t) \quad (6)$$

Decomposing the time-dependent cosine terms into complex exponentials, the Fourier expansion (with Fourier coefficients $d_{jk}^{(n)}$) is obtained:

$$D_{jk}(t) = \sum_{n=-2}^{+2} d_{jk}^{(n)} [\exp(in\omega_r t)] \quad (7)$$

Figure 4 Coordinate frame of reference for a sample spinning around the axis ω_r , and the vector r_{jk} rotating with a polar angle $\omega_r t$

The first term on the right-hand side of equation (6) is time independent [Fourier coefficient $d_{jk}^{(0)}$ in equation (7)], and becomes equal to zero for $\theta_m = 54.7^\circ$ —this is called the ‘magic angle’. The other two terms in equation (6) show that sample rotation results in a modulation of the dipolar coupling strengths D_{jk} with spinning frequencies ω_r and $2\omega_r$ and an average value equal to zero. Therefore, under sample rotation the dipolar Hamiltonians $\hat{\mathcal{H}}_{II}$ and $\hat{\mathcal{H}}_{IS}$ become periodically time-dependent with the period $2\pi/\omega_r$ of sample rotation.

5 CROSS POLARIZATION IN ROTATING SOLIDS²⁸

As illustrated in Section 3, the CP rate, as a function of the transition probabilities of I – S flip-flop transitions, and the form of the CP-matching curve depend on the I – S and I – I dipolar coupling strengths. In order to proceed with the quantum mechanical model discussed above, the resulting time periodicity of dipolar Hamiltonians originating from MAS has to be included. For an isolated I – S spin system in the presence of sample spinning the problem can be solved, for example, using the Floquet formalism (see *Floquet Theory*).^{15,16} Within this theory, originally proposed as a general method for solving linear differential equations with periodic coefficients, an average Hamiltonian, called the Floquet Hamiltonian, can be derived by using the Fourier decomposition of the periodic time-dependent dipolar coupling strengths [equation (7)]. For very fast sample spinning (i.e. when the MAS frequency ω_r is comparable to or larger than the dipolar coupling coefficients $d_{jk}^{(n)}$, $n = \pm 1$ or ± 2), the flip-flop transitions responsible for I – S magnetization transfer are subject to conditions which are more rigorous than the selection rules given in equation (4), because they now include the MAS frequency ω_r .¹⁶

$$\Delta m_I + \Delta m_S = 0, \quad |\Delta\Omega + n\omega_r| \leq \frac{1}{2}d_{jk}^{(n)}, \quad n = \pm 1, \pm 2 \quad (8)$$

which means, that CP is possible for mismatch values $\Delta\Omega = \pm\omega_r$ and $\pm 2\omega_r$, and becomes small for $n = 0$ because of the disappearance of the zero-order Fourier coefficient $d_{jk}^{(0)}$ at the magic angle [see equations (5)–(7)]. From the conditions given in equation (8), it follows that the CP-matching curve,

Figure 5 CP-matching curves for various spinning rates for a solid with relatively weak dipolar couplings, e.g. hexamethylbenzene

being rather broad and featureless for a nonrotating solid [Figure 3(b)], splits into sidebands separated by the MAS frequency ω_r , as shown in Figure 5. For very fast spinning, maximum CP does not occur at $\Delta\Omega = 0$, as in the static case, but takes place at $\Delta\Omega$ close to the first and second-order sidebands. The widths of these sidebands depend on the dipolar coupling parameters $d_{jk}^{(n)}$ ($n \neq 0$), and on ω_r as increasing spinning rates provide a more complete averaging of dipolar couplings. The CP-matching curves shown in Figure 5 are calculated by means of a statistical theory,¹⁷ taking into account that: (1) in a solid, usually many I spins interact with each other; and (2) each S spin may be coupled to more than one I spin. The dipolar couplings are introduced as parameters, which represent average values for the I and S spin systems (so-called ‘second moments’¹²), while the spin dynamics are described by statistical spin-correlation functions.

Experimental evidence for the break-up of the CP-matching curve into a sideband pattern was first provided by Stejskal et al.¹⁸ for adamantane. Many other examples of CP-matching behavior under MAS have been found experimentally.^{19–22} Figure 6 shows the ^1H – ^{13}C CP matching curve for aromatic carbon in polycrystalline hexamethylbenzene (HMB) obtained at a spinning rate of $\omega_r/2\pi = 5$ kHz. In this experiment the

Figure 6 CP-matching curves for aromatic ^{13}C nuclei in hexamethylbenzene: (a) experimental curve obtained at $\omega_r/2\pi = 5$ kHz; (b) theoretical curve

proton rf field was fixed at $\Omega_{1I}/2\pi = 40$ kHz and the ^{13}C rf field was varied in the range $\Omega_{1S}/2\pi = 18$ to 57 kHz. Each experimental data point in Figure 6 represents an intensity value of the ^{13}C NMR line resonating at ca. 130 ppm (isotropic chemical shift relative to tetramethylsilane), attributed to aromatic carbon nuclei in HMB. The theoretical curve was obtained¹⁷ using values for the $I-I$ and $I-S$ dipolar coupling parameters determined from the internuclear distances and the crystal structure of HMB.

The appearance of sharp CP-matching sidebands at high spinning rates causes various experimental difficulties. First, the maximum of S -spin magnetization is not obtained at $\Delta\Omega = 0$, as for the static case. The mismatch has to be adjusted to one of the sidebands, the location of which depends on ω_r . Second, the sidebands become narrow at high MAS rates, requiring highly stable rf amplitudes Ω_{1I} and Ω_{1S} , and accurate spinning rates which have to remain constant over extended periods of time. Otherwise, slight deviations lead to dramatic losses of the CP enhancement for S -spin magnetization. Furthermore, the spectrum of the S spins may possess a variety of resonance lines with different resonance frequencies; for example, ^{13}C NMR spectra of organic solids very often reveal resonance frequencies over a range of 200 ppm, which leads to resonance offsets resulting in different mismatch values $\Delta\Omega$ for each resonance line. This means that some S spins are properly cross polarized, while other S spins with different $\Delta\Omega$ values due to resonance offsets are only weakly polarized. Any of the latter cases results in distortions of the relative intensities in CP MAS spectra.

6 MODIFIED CP EXPERIMENTS AND MAS

Because of the usefulness of the CP MAS technique, much effort has been made in recent years to develop methods which circumvent the experimental disadvantage originating from the Hartmann–Hahn condition under MAS. These methods can be grouped as follows:

1. Mechanical techniques, for example, off-magic angle spinning²⁰ and stop-and-go magic angle spinning.²¹
2. Techniques based on modifications of the standard CP rf-pulse scheme (Figure 1), including rf phase or amplitude modulation,^{16,23,24} or rf amplitude variation.²⁵
3. Alternative ways of magnetization transfer, for example, via the nuclear solid effect,^{8,12} or dynamic nuclear polarization.^{12,26}

The following brief discussion will focus on methods (1) and (2).

Off-magic angle spinning exploits the fact that the zero-order coefficients $d_{jk}^{(0)}$ of the Fourier expansion [equation (7)] become unequal to zero for spinning angles θ different from the magic angle θ_m , which should lead to an increase in the CP-matching centerband (at high spinning rates) and to a broadening of the center- and sidebands. Sardashti and Maciel²⁰ employed a CP technique, using the angle $\theta = 90^\circ$ during the CP period, and switching to the magic angle before starting acquisition of the NMR signal. According to equation (6), only centerbands and second-order sidebands appear in the CP-matching curve. A broadening of the center- and sidebands originating from the less severe averaging of $I-I$ dipolar couplings for $\theta \neq \theta_m$ is also observed in this experiment.

Figure 7 CP pulse sequence with simultaneous phase inversion

Stop-and-go sample spinning, proposed by Zeigler et al.,²¹ is even more straightforward in its attempt to avoid CP-matching sidebands. During the CP period the sample is not spinning, or it is slowed down, while during detection MAS is turned on. Both techniques require advanced mechanical capabilities for the spinner system, either being able quickly to switch the spinner axis or to turn the spinning on and off during the CP experiment.

A general way to improve the magnetization transfer under MAS conditions is based on modifications of the CP rf-irradiation scheme.^{16,23–25} One possibility²⁵ consists of applying stepwise rf-amplitude variations of the spin lock field [variable amplitude CP (VACP)], thus creating a whole series of slightly different Hartmann–Hahn matching conditions during one CP period. In this way an averaging over rf-amplitude mismatches is achieved, resulting in a remarkable smoothing of CP-matching curves. Another strategy, which may give an idea of the general philosophy involved, introduces an additional time dependence into the CP Hamiltonian [equation (2)] by periodically inverting the phases of the rf fields in the I and S spin channels simultaneously,^{16,23,24} synchronized with sample spinning (Figure 7). The time dependence of the TRF Hamiltonian then originates from: (1) the MAS modulation of the dipolar interactions, and (2) the modulation of the rf fields. One effect of this pulse sequence, which is important from a practical point of view, consists of averaging or compensating for $\Delta\Omega$ deviations due to rf inhomogeneities.^{24,27} The pulse sequence of Figure 7 has been shown to provide a significant broadening of the CP-matching curve.^{16,24} Improvements have been proposed¹⁶ leading to a whole new class of general amplitude-modulation CP (AMCP) schemes based on the study of detailed time dependences of the TRF Hamiltonian, and allowing the design of pulse sequences to restore CP-matching conditions under MAS, which are similar to those in nonrotating solids.

1 INTRODUCTION

A number of techniques exist for producing well resolved NMR spectra of solid samples. Some, including very rapid rotation about the ‘magic’ angle¹ of 54.7° and CRAMPS (see *CRAMPS*) multiple pulse irradiation, attempt to produce well resolved spectra of abundant nuclei such as ¹H or ¹⁹F. However, much greater success has been achieved in obtaining high-resolution solid state spectra of ‘rare’ NMR isotopes such as ¹³C and ¹⁵N. Typically, three techniques are combined: cross polarization² to increase signal strength and measurement repetition rate, heteronuclear decoupling³ to remove line broadening due to surrounding abundant spins, and magic angle spinning⁴ to eliminate chemical shift anisotropy (CSA) effects.

This article deals primarily with cross polarization in solids. Heteronuclear decoupling and magic angle spinning are briefly mentioned, but more detailed discussions of these techniques are presented in other articles (see *Magic Angle Spinning* and *Rotating Solids*).

2 STRATEGIES FOR ACHIEVING HIGH-RESOLUTION NMR IN SOLIDS

It is helpful to begin by considering the various interactions that occur in the solid state.⁵ In order of their relative magnitudes, the interactions may be summarized as follows:

1. *Quadrupolar* This is an interaction involving electric field gradients that occurs only for nuclei of spin quantum number greater than $\frac{1}{2}$. Since most important NMR nuclei, including ¹H, have spin- $\frac{1}{2}$, they are not subject to quadrupolar effects.
2. *Dipolar* This is the effect that the nuclear dipole field generated by each nuclear spin has on its neighboring spins, and it is the dominant interaction for abundant nuclei such as ¹H spins in solids. Dipolar interactions are often referred to as either ‘homonuclear’, for interaction between nuclei of the same species (e.g. ¹H–¹H), or heteronuclear, for interaction between nuclei of different

species (e.g. ¹H–¹³C). Due to rapid, isotropic molecular motion, dipolar interactions are averaged to zero in liquids, but do contribute to the longitudinal relaxation parameter T_1 .

3. *Chemical Shift Anisotropy (CSA)* The magnitude of the diamagnetic effect that surrounding electrons have on the nucleus usually depends on molecular orientation. The average, or isotropic, shift is observable in both liquids and solids. In addition, resonance lines for most solids exhibit an additional shift based on molecular orientation. For single crystals this is manifested as a dependence of the resonance frequency on orientation. For a powder sample, all orientations are represented simultaneously and the result is a broad CSA ‘powder pattern’. These powder patterns often overlap and cause loss of resolution.
4. *Isotropic Chemical Shift* In a liquid, rapid molecular reorientation allows only the average, or isotropic chemical shift to be observed. In solids, the same result is often achieved by rapid rotation of the sample about an axis tilted away from the magnetic field by 54.7°, often referred to as the ‘magic’ angle. Magic angle spinning is discussed in more detail in other articles (see *Magic Angle Spinning* and *Rotating Solids*).
5. *J Coupling* This is an indirect coupling of nuclei to each other, mediated by shared electrons. As such, it is a ‘through-bond’ coupling, and is of great importance in liquids. However, it is too weak to be observable in most spectra of solids.

Elimination of the direct dipolar interaction between nuclei is clearly the first step in achieving high-resolution NMR in solids. The dipolar interaction between a given pair of spin- $\frac{1}{2}$ nuclei, as expressed by the dipolar Hamiltonian⁶ $\hat{\mathcal{H}}_D$, can be written as

$$\hat{\mathcal{H}}_D \propto \left(\frac{1}{r^3} \right) (1 - 3 \cos^2 \theta) \text{ spin part} \quad (1)$$

where r is the internuclear distance, and θ is the angle that the internuclear vector makes with the magnetic field. The ‘spin part’ varies, depending on whether the two nuclei are of the same species (homonuclear) or different species (heteronuclear). For example, the spin part for two coupled ¹H spins is given by:

$$\text{Homonuclear spin part} = \{\hat{I}_1 \cdot \hat{I}_2 - 3\hat{I}_{z1}\hat{I}_{z2}\} \quad (2)$$

where the labels 1 and 2 refer to the two ¹H spins. On the other hand, the spin part for dipolar coupling between a ¹H and a ¹³C nucleus is given by:

$$\text{Heteronuclear spin part} = \{\hat{I}_z \hat{S}_z\} \quad (3)$$

where I and S refer to the ¹H and ¹³C nuclei, respectively.

Clearly, the dipolar interaction may be eliminated by causing any of the three terms in equation (1) to vanish. In some cases, rapid rotation of the sample about the magic angle can be used to eliminate the second term.⁷ However, for most rigid solids it is usually not possible to spin fast enough for this approach to be effective in eliminating dipolar couplings. For heteronuclear coupling, the spin part can usually be eliminated by strong rf irradiation of one of the nuclear

species,³ whereas for homonuclear coupling the spin part can sometimes be sufficiently reduced by the CRAMPS multiple rf pulse technique (see **CRAMPS**).

The most commonly used approach is to observe a nuclear spin for which the NMR active isotope has a low abundance. For these ‘rare’ spins, such as ¹³C, the homonuclear coupling is automatically eliminated since the large distances between NMR active nuclei cause the first term of equation (1) to be vanishingly small. At the same time, the heteronuclear interaction with surrounding abundant spins, usually ¹H nuclei, is eliminated by strong continuous rf irradiation³ of the abundant nuclei to cause the spin part given in equation (3) to average to zero. For powder samples, magic angle spinning is also applied to eliminate CSA broadening.

There are two important disadvantages associated with NMR of rare nuclei in solids, namely low sensitivity and, in most cases, long relaxation times. The low sensitivity is an obvious result of low natural abundance.

The long relaxation times,⁸ or T_1 values, are essentially due to an accident of nature. For spin- $\frac{1}{2}$ nuclei, the nuclear spin energy is coupled to the surrounding environment, or ‘lattice’, via locally generated time varying magnetic fields. The strength of the coupling, and therefore the rate at which the nuclear spins return to equilibrium, is governed by the magnetogyric ratio. Unfortunately, all of the spin- $\frac{1}{2}$ NMR nuclei with rare isotopic abundance have relatively low gyromagnetic ratios, and therefore long relaxation times, compared with the most commonly observed abundant NMR spins, namely ¹H, ¹⁹F, and ³¹P.

Low sensitivity can be improved by using a very high magnetic field, but the expense is often prohibitive and, for some nuclei, especially ¹³C, a very high field can make it difficult or impossible to eliminate CSA effects. Another approach is to enrich isotopically the rare nucleus to a higher abundance. This approach can be very successful for improving sensitivity and for spectral editing, but it can also be very time consuming and expensive. In addition, enrichment beyond approximately 10% can cause broadening due to dipolar interactions between the ‘rare’ nuclei.

T_1 can sometimes be reduced by introducing paramagnetic impurities⁹ into the sample, or in some cases by varying the sample temperature. However, these are inconvenient and specialized techniques.

The most commonly used method for increasing the sensitivity and experiment repetition rate when observing rare spins in solids is to transfer polarization from surrounding abundant spins, usually ¹H nuclei, to the rare spins. This is referred to as ‘cross polarization’. Cross polarization not only enhances the signal strength of the rare spins, but also allows the experiment to be repeated at a rate governed by the T_1 of the abundant spins.

3 THEORY OF CROSS POLARIZATION IN SOLIDS

At equilibrium, the degree of nuclear polarization P_0 depends on the strength of the applied magnetic field B_0 , the magnetogyric ratio γ , and the ‘lattice’ temperature T_L :²

$$P_0 \propto \frac{\gamma B_0}{k T_L} \quad (4)$$

where k is Boltzmann’s constant. The polarizations of different nuclear species will therefore be proportional to their magnetogyric ratios:

$$\frac{P_{0I}}{P_{0S}} = \frac{\gamma_I}{\gamma_S} \quad (5)$$

The key to understanding cross polarization in solids is the concept of mutual spin flips. This is a process whereby two coupled spins undergo simultaneous, opposite transitions in their spin states. Essentially, one spin makes a transition from ‘spin up’ to ‘spin down’, while the other goes from ‘spin down’ to ‘spin up’. This process occurs spontaneously among abundant nuclei in solids. Since the total polarization is unchanged, the process conserves energy, and the spin part of the homonuclear dipolar coupling contains appropriate mutual spin flip terms. In order to show this better, equation (2) can be rewritten in terms of raising and lowering operators:

$$\text{Homonuclear spin part} = \left\{ \frac{1}{2} [\hat{I}_+ \hat{S}_- + \hat{I}_- \hat{S}_+ - 2 \hat{I}_z \hat{S}_z] \right\} \quad (6)$$

Because of this process of mutual spin flips, which is often referred to as nuclear ‘spin diffusion’, abundant spins tend to maintain a uniform degree of polarization despite localized perturbations such as paramagnetic impurities. For this reason, they are often described as a ‘thermodynamic bath’ of spins with an effective spin ‘temperature’.

Of course, mutual spin flips do not occur between rare spins since they are not coupled to each other. Also, they do not occur spontaneously between nuclei of different species, since a mutual spin flip of this sort does not conserve energy, and the spin part given in equation (3) does not contain the necessary raising and lowering operators.

Cross polarization in solids is normally achieved by using rf irradiation to induce heteronuclear mutual spin flips. Since the abundant spins far outnumber the rare spins, this process causes the polarization of the rare spins to be made equal to that of the abundant spins. According to equation (5) this means that the polarization of the rare spins is increased by a factor equal to the ratio of their magnetogyric ratios. For coupled ¹H and ¹³C spins, the ratio is approximately 4. Due to relaxation phenomena and other imperfections, a polarization enhancement factor of 3 is more typically achieved.

The basic method for inducing mutual spin flips between different nuclear species was introduced by Hartmann and Hahn, and is commonly called ‘Hartmann–Hahn’ cross polarization.¹⁰ The pulse sequence is shown in Figure 1. An initial I -spin pulse places the I magnetization along the y axis in the I -spin rotating frame. This is followed by continuous irradiation along y in the I frame, together with simultaneous irradiation of the S spins. The rf power levels for the two nuclear species are adjusted such that the ‘Hartmann–Hahn’ condition is met:

$$\omega_{1I} \equiv \gamma_I B_{1I} = \gamma_S B_{1S} \equiv \omega_{1S} \quad (7)$$

In practical terms, this means that the length of a $\pi/2$ pulse is the same for both spin systems. During a few milliseconds of simultaneous irradiation, a substantial magnetization develops along the irradiation axis in the S -spin rotating frame. In

order to acquire a FID, it is then only necessary to turn off the rf on the S channel and observe the signal while the I -spin irradiation is continued for the purpose of heteronuclear decoupling.

Figure 1 Basic pulse sequence for Hartmann-Hahn cross polarization

Hartmann-Hahn cross polarization can best be understood by carrying out a few simple quantum mechanical manipulations. In the doubly rotating reference frame of the Zeeman interactions for spins I and S , the Hamiltonian for the system may be written as:

$$\hat{\mathcal{H}}_R = \omega_I \hat{I}_Y + \omega_S \hat{S}_Y + \beta_{IS} \hat{I}_z \hat{S}_z \quad (8)$$

where ω_1 is the rf nutation frequency, β_{IS} is a constant, and all other Hamiltonian terms such as chemical shift have been omitted for the sake of clarity. When the Hartmann-Hahn condition is matched, $\omega_I = \omega_S$, and equation (8) may be written as:

$$\hat{\mathcal{H}}_R = \omega_1 (\hat{I}_Y + \hat{S}_Y) + \beta_{IS} \hat{I}_z \hat{S}_z \quad (9)$$

The two terms in equation (9) do not commute, but if $\omega_1 \gg \beta_{IS}$ the situation can be further simplified by transforming to the frame of the interaction $(I_y + S_y)\omega_1$. The Hamiltonian in this frame is:

$$\begin{aligned} \hat{\mathcal{H}}_R^I &= \beta_{IS} [\hat{I}_z \cos(\omega_1 t) + \hat{I}_x \sin(\omega_1 t)] \\ &\quad \times [\hat{S}_z \cos(\omega_1 t) + \hat{S}_x \sin(\omega_1 t)] \end{aligned} \quad (10)$$

Keeping only the time independent, ‘secular’ part gives:

$$\hat{\mathcal{H}}_R^I = \frac{1}{2} \beta_{IS} [\hat{I}_z \hat{S}_z + \hat{I}_x \hat{S}_x] \quad (11)$$

which is the first order average Hamiltonian, and commutes with the major interaction $\omega_1(I_y + S_y)$.

The significance of $\hat{\mathcal{H}}_R^I$ can be better seen if both the I and S coordinate axes are tilted by 90° , such that I_z' and S_z' are parallel with the applied rf fields, i.e. they point along I_y and S_y , which is to say the axis of quantization has been changed to the direction along I_y, S_y . In this doubly tilted frame, the Hamiltonian becomes

$$\hat{\mathcal{H}}_R^{I'} = \frac{1}{2} \beta_{IS} (\hat{I}_x \hat{S}_x + \hat{I}_y \hat{S}_y) \quad (12)$$

which can be rewritten in terms of raising and lowering operators as:

$$\hat{\mathcal{H}}_R^{I'} = \frac{1}{4} \beta_{IS} (\hat{I}_+ \hat{S}_- + \hat{I}_- \hat{S}_+) \quad (13)$$

Clearly, mutual spin flips will occur under these circumstances, but they will occur between magnetization aligned along the y axes in the I and S spin reference frames. Note that if the Hartmann-Hahn condition is not met, there is no secular part in equation (11), and the effect of simultaneous irradiation will simply be to eliminate the heteronuclear coupling.

This simple quantum mechanical treatment applies strictly to an isolated pair of spins. In such a case, the result of Hartmann-Hahn irradiation is an oscillation of magnetization between the two spins. However, in most cases the I spin is coupled to a large number of other I spins via homonuclear dipolar coupling. This coupling to a ‘bath’ of I spins quickly damps out any oscillation and results in a smooth buildup of S spin magnetization along the y axis.

Note that a similar quantum mechanical treatment may be used to show that application of CW irradiation to two spins coupled by homonuclear dipolar coupling yields an effective Hamiltonian that remains dipolar in form but is rotated in spin space and reduced in magnitude by a factor of 2. The result is that CW rf irradiation slows, but does not quench, spin diffusion between the I spins.

The rate of polarization buildup in the S spins will be governed by the strength of the heteronuclear coupling and by the rate of I spin diffusion. The characteristic time for this process¹¹ is often called T_{CH} , emphasizing the fact that the method is most commonly applied to cross polarization of ^{13}C spins coupled to ^1H spins. At the same time that the S spin polarization is growing, the I spin polarization will tend to decay according to the characteristic ‘spin locked’ or ‘rotating frame’ relaxation time¹² $T_{1\rho}$. The competition between these two rates will determine what level of polarization enhancement is actually achieved, how critical the cross polarization time is, and how quantitative the resulting spectrum will be.

Figure 2 presents two ^{13}C spectra of glycine, both obtained with magic angle spinning and heteronuclear decoupling and equal numbers of scans. The first spectrum shows the sensitivity obtained without cross polarization, while the second shows the spectrum obtained using Hartmann-Hahn cross polarization. It can be seen from Figure 2 that a substantial increase in signal strength is realized, although not quite the theoretical increase of 4. Also, a slight perturbation in the relative intensities of the resonance lines is evident. This is due to different values of T_{CH} and $T_{1\rho}$ for the two

Figure 2 Comparison of ^{13}C MAS spectra for glycine obtained by (a) block decay (single pulse) with heteronuclear decoupling, and (b) Hartmann–Hahn cross polarization followed by heteronuclear decoupling

lines. When multiple scans are to be accumulated, an additional gain in sensitivity is realized due to the shorter relaxation time, or T_1 , of the ^1H spins in glycine as compared with the ^{13}C spins (approximately 3 s as compared to 30 s). Figure 3 presents the ' T_{CH} ' polarization curve for Hartmann–Hahn cross polarization of glycine. The effects of the competing T_{CH} and $T_{1\rho}$ time constants can easily be seen from the figure.

Figure 3 T_{CH} cross polarization curves for glycine

It should be pointed out that Hartmann–Hahn cross polarization can also be described in thermodynamic terms.¹³ The abundant I spins are treated as a 'bath', with a 'spin' temperature determined by the degree of polarization and the energy associated with a nuclear spin state transition, i.e. spin

'flip'. Although the S spins are not in direct contact with each other, they are also treated as if they were a thermodynamic bath, and their low abundance is incorporated by assigning them a very low heat capacity. During the Hartmann–Hahn cross polarization period, the I and S spins are quantized along y , and are said to have spin temperatures determined by their polarizations and the strengths of the applied rf fields. The Hartmann–Hahn irradiation has the effect of thermally connecting the two spin baths and, since the S spins have very low heat capacity, they tend to approach the I spin temperature. As the rf fields are equal (in units of 1/second), equal temperatures imply equal degrees of polarization.

It should also be pointed out that there are other methods of cross polarization in solids. One approach uses rf irradiation with adiabatically varied amplitude to transfer magnetization via a 'dipolar' polarization state.^{14,15} Another uses the 'Jener–Brockhard' pulse sequence to transfer polarization via multiple quantum states.¹⁶ Still others transfer magnetization using nonthermodynamic techniques similar to those commonly used for liquids.¹⁷ However, all of these alternative techniques have significant disadvantages in comparison with Hartmann–Hahn cross polarization, and none of them is widely used.

4 CROSS POLARIZATION AT HIGH SPINNING SPEEDS

As was mentioned in the introduction, cross polarization in solids is usually combined with magic angle spinning in order to eliminate chemical shift anisotropies, or CSAs. This combined experiment is often called CP MAS, and it is without doubt the most commonly used experimental method in solid state NMR.

In order completely to eliminate CSA effects, the MAS spinning rate must be faster than the width (in hertz) of the broadest CSA pattern in the spectrum. CSA magnitudes depend heavily on the nuclear species and chemical environment. For example, CSAs for ^{15}N and ^{29}Si are typically less than 20 ppm, while CSAs for ^{31}P can be as large as 300 ppm or more. For ^{13}C ,

Figure 4 Glycine ^{13}C spectrum with slow spinning MAS. The spinning sidebands approximately trace out the CSA pattern

Figure 5 Glycine CP MAS signal strength as a function of Hartmann–Hahn mismatch and spinning speed. The match condition breaks into mismatch sidebands as the spinning speed is increased

CSA widths range from a few parts per million for methyl carbons atoms to 150 ppm or more for rigid aromatic carbon atoms.

If the MAS spinning rate is smaller than the CSA width, the CSA pattern breaks into ‘sidebands’ that are spaced at the MAS rate and approximately trace out the CSA pattern.¹⁸ An example of this is presented in Figure 4 for glycine. A small number of sidebands can generally be tolerated, especially in highly crystalline samples like glycine that yield spectra with sharp lines. In fact, well resolved sidebands can be analyzed to extract the principal values of the CSA tensor.¹⁸ Nevertheless, it is usually desirable to minimize the occurrence of CSA spinning sidebands by spinning rapidly. Since the CSA width is proportional to the magnetic field strength, the need for fast magic angle spinning increases at higher fields.

MAS spinning above approximately 20 kHz is a difficult mechanical and materials problem, and it also interferes with cross polarization because it tends to suppress heteronuclear dipolar coupling. Although the spinning rate is rarely fast enough completely to eliminate dipolar coupling, it is often sufficient to cause the Hartmann–Hahn match condition to become very critical and inefficient. As the spinning rate increases, additional ‘match’ conditions appear,¹⁹ making it possible to cross polarize when the rf strength of one channel is mismatched from the other by either one or two times the spinning rate.

At very high spinning speeds, cross polarization under these special mismatched conditions remains relatively efficient, even when almost no cross polarization is possible under normal matched conditions. An example of this high speed spinning effect for ^{13}C in glycine is shown in Figure 5.

Figure 6 Pulse sequence using alternating π pulses to improve cross polarization during high speed MAS

Figure 7 Variable amplitude cross polarization pulse sequence as it was originally proposed. The 'stair step' rf amplitude variation may be replaced by other functions such as a ramp or 'sawtooth'

that will provide sufficient signal intensity and yet will not overly complicate the data analysis by introducing too many spinning sidebands. Typically, CP MAS spectra of ^{13}C are measured in NMR spectrometers with ^1H resonance frequencies of 200–300 MHz, and are rarely attempted above 400 MHz. MAS rates are usually kept in the range 4–8 kHz, although spinning up to 15 kHz and beyond is not mechanically difficult. Even under these optimum conditions, ^{13}C CP MAS spectra of rigid solids are rarely free of CSA sidebands.

Several methods have been proposed to improve cross polarization during high speed spinning. In some, the spinning rate²⁰ or even the spinning angle²¹ is changed between the cross polarization and signal detection phases of the experiment. Other approaches use 180° rf pulses to 'spoil' MAS dipolar suppression during the cross polarization²². A typical pulse sequence for this method is shown in Figure 6.

Figure 8 Glycine VACP signal strength as a function of Hartmann–Hahn mismatch and spinning speed.

Unfortunately, it is difficult to achieve stable and reproducible results using mismatched Hartmann–Hahn cross polarization, because the mismatched conditions are very critical and strongly dependent on the spinning rate.

Because of the problems associated with high speed spinning, it is often necessary to select a magnetic field strength

The technique that currently appears to offer the greatest promise for cross polarization at high spinning speeds is called 'variable amplitude cross polarization' (VACP).²³ A diagram of the experiment as it was originally introduced is shown in Figure 7. Essentially, the method depends on the fact that, in many cases, especially for ^{13}C in most

samples, the cross polarization rate T_{CH} is much faster than $T_{1\rho}$. Therefore, there is time to vary the rf levels over a range of values, essentially searching for one or more of the special mismatched Hartmann–Hahn conditions. At most rf settings, no match will occur and the I and S spins will simply remain ‘spin locked’. Hopefully, however, at least one of the rf level settings will be near enough to a mismatched Hartmann–Hahn condition to result in significant cross polarization.

For many samples, VACP works very well. An example is given in Figure 8 for glycine spinning at 15 kHz. For experimental convenience, the ‘stair step’ approach illustrated in Figure 7 is often replaced by a simple amplitude ramp, and the range of rf levels is made large enough to extend from the exact Hartmann–Hahn match to an offset of twice the MAS frequency. Typical VACP cross polarization times are 10–20 ms, as compared to 1–5 ms for traditional Hartmann–Hahn cross polarization.

5 SPECTRAL EDITING AND OTHER TRICKS USING CROSS POLARIZATION

Experiments that serve to identify what functional group a given resonance belongs to are commonly referred to as ‘spectral editing’ techniques (see *Spectral Editing Techniques: Hydrocarbon Solids*). This is because they normally cause certain lines in the spectrum to be suppressed or inverted. There are several variations of the Hartmann–Hahn cross polarization method that are useful for spectral editing. Two examples that identify CH_2 carbon resonances are reverse polarization,²⁴ which depends on differences in T_{CH} , and WIMSE,²⁵ which uses a sophisticated heteronuclear multiple pulse cross polarization technique known as ‘windowless isotropic mixing’ or ‘WIM’.²⁶ Whereas most spectral editing methods depend on differences in coupling strength or polarization time, WIMSE makes use of basic differences in spin dynamics. During WIM cross polarization the I spins are isolated from each other, and a dynamic rather than thermodynamic behavior results. A diagram of the WIMSE experiment is presented in Figure 9, and WIMSE spectra of solid gelatin are presented in Figure 10.

WIM cross polarization is also very useful for heteronuclear two-dimensional spectroscopy in solids.²⁷ A diagram of the WIM based two-dimensional HETCOR experiment is presented in Figure 11. During the first part of this experiment, the BLEW-24 and BB-24 multiple pulse sequences are used to suppress both the homonuclear and heteronuclear dipolar couplings. As a result, the I spins evolve only under

Figure 9 WIMSE spectral editing pulse sequence

Figure 10 WIMSE spectra for solid gelatin showing only CH_2 resonances (top), carbonyl, CH and CH_3 resonances (middle) and all resonances (bottom)

Figure 11 Two-dimensional HETCOR pulse sequence

the influence of resonance offset and chemical shift. The magnetization is then cross polarized to the S spins using WIM, and the S signal is detected. An example of two-dimensional HETCOR applied to ibuprofen is presented in Figure 12. Because WIM is used for cross polarization, peaks occur in the spectrum only at positions that correlate directly coupled 1H – ^{13}C spins. If the usual Hartmann–Hahn method were used, rapid 1H spin diffusion would occur during the cross polarization time, and ‘cross peaks’ would appear for all possible combinations of 1H and ^{13}C .

A number of other methods have been used to isolate spin groups during cross polarization, including simultaneously applied CPMAS pulse sequences,²⁸ frequency switched Lee–Goldburg irradiation,²⁹ and very rapid Hartmann–Hahn irradiation.³⁰ So far, WIM appears to be the most successful of these methods.

Figure 12 Two-dimensional HETCOR spectrum of ibuprofen. The one-dimensional spectra shown along the axes are a BR-24 CRAMPS spectrum (vertical) and a conventional CP MAS spectrum (horizontal) which were obtained in separate measurements

6 CONCLUSIONS

Hartmann–Hahn cross polarization is widely used to improve sensitivity and experiment repetition rate for rare spins in solids. Although some loss of quantitative information often occurs, the benefits usually far outweigh the disadvantages. At high MAS spinning speeds, cross polarization becomes problematic, but the recently introduced variable amplitude method appears to reduce greatly these difficulties in many cases. A variety of specialized techniques based on Hartmann–Hahn cross polarization have been developed, including spectral editing methods and pulse sequences that suppress spin diffusion during cross polarization.

1 INTRODUCTION

The application of dipolar spectroscopy as a structural tool in solids can be realized with the help of transient nutations and other similar techniques. The main objective is to take advantage of the unambiguous geometric and dynamical interpretation of purely homonuclear dipolar spectra involving a small number of interacting spins. Thus, the requirements to be met not only involve the removal of broadening caused, for example, by shielding interactions and static field inhomogeneities, but also that homonuclear dipolar couplings remain either unchanged or are affected in a easily accountable way.

Dipolar spectroscopy in solids using transient nutations was pioneered by Yannoni and Kendrick¹ as a method for obtaining structural information in systems where the lack of some degree of long-range order excludes the use of diffraction techniques. The method, which involves enrichment of an isotopically rare spin- $\frac{1}{2}$ nucleus at two selected molecular positions, followed by dilution of the pairs either in the unenriched material or in a matrix, is ideally suited for structural studies in amorphous solids, reaction intermediates, catalysts, etc.

Transient nutation is just one of the available strategies for dipolar spectroscopy in solids. The suppression of inhomogeneous broadening can also be achieved by employing a train of properly chosen rf pulses. Of the possible pulse sequences, the venerable Carr–Purcell sequence² and its variations, with some additions and corrections, has also been shown³ to be quite effective as a structural tool in disordered solids, giving some advantage in overall spectral resolution.

2 DIPOLAR SPECTROSCOPY OF ISOLATED PAIRS

In order to extract useful geometrical and dynamical information in disordered solids from the homonuclear magnetic dipole–dipole interaction, it is required that the spectra contain sharp and well-defined features, even when the dipoles

are randomly oriented. This can be achieved, for example, by creating small clusters of mutually interacting dipoles through isotopic enrichment and matrix isolation or dilution. The simplest strategy is to attempt to approximate a regime of isolated pairs.

For a pair of identical nuclear spins I_1 and I_2 and magnetogyric constant γ in a strong magnetic field $B_0 = \omega_0/\gamma$ along the z axis, the secular⁴ Hamiltonian $\hat{\mathcal{H}}_{12}$ involving Zeeman and dipolar interactions can be written as

$$\hat{\mathcal{H}}_{12} = -\hbar\omega_0(\hat{I}_{z1} + \hat{I}_{z2}) + A_{12}(\hat{I}_1 \cdot \hat{I}_2 - 3\hat{I}_{z1}\hat{I}_{z2}) \quad (1)$$

where

$$A_{12} = \hbar^2\gamma^2(3\cos^2\theta_{12} - 1)/2r_{12}^3 = \hbar^2\gamma^2 P_2(\cos\theta_{12})/r_{12}^3 \quad (2)$$

$P_2(\cos\theta_{12})$ in equation (2) denotes a second-order Legendre polynomial, r_{12} represents the internuclear vector, and θ_{12} is the angle between r_{12} and B_0 .

The eigenfunctions and eigenvalues of $\hat{\mathcal{H}}_{12}$ for spin- $\frac{1}{2}$ nuclei can be verified from equation (1) to be the triplet states $|t_{\pm}\rangle = |+\rangle|+\rangle$, $|t_{-}\rangle = |-\rangle|-\rangle$ and $|t_0\rangle = (|+\rangle|-\rangle + |-\rangle|+\rangle)/\sqrt{2}$, with energies $E_{t+} = \hbar\omega_0 + A_{12}/2$, $E_{t-} = -\hbar\omega_0 + A_{12}/2$, and $E_{t0} = -A_{12}$, respectively, and the singlet state $|s_0\rangle = (|+\rangle|-\rangle - |-\rangle|+\rangle)/\sqrt{2}$ with energy $E_{s0} = 0$. Since the latter is not connected to the triplet states by a rf magnetic field, the spectrum consists of only two lines, the famous Pake⁵ doublet, with a frequency separation given by:

$$\begin{aligned} \delta\nu_p &= 3\hbar\gamma^2(3\cos^2\theta_{12} - 1)/4\pi r_{12}^3 \\ &= 3\hbar\gamma^2 P_2(\cos\theta_{12})/2\pi r_{12}^3 \end{aligned} \quad (3)$$

Most important as a structural tool in systems lacking long-range order is the spectrum of randomly oriented isolated pairs of spin- $\frac{1}{2}$ nuclei. It can be obtained from equation (3) under the assumption of vectors r/r uniformly distributed on a unit sphere. The spectral weight in the frequency interval $d\nu$ is then proportional to the solid angle $2\pi \sin\theta d\theta$ and to $1/(d\nu/d\theta)$, where $\nu - \nu_0 = \pm\delta\nu_p/2$ [equation (3)] are the positions of the two members of the Pake doublet relative to the Larmor frequency $\nu_0 = (\gamma/2\pi)B_0$. Thus, the frequency spectrum for randomly oriented⁵ isolated pairs can be seen to be proportional to $1/|\cos\theta|$ and, consequently, to display singularities for $\theta = \pi/2$ corresponding to $\nu - \nu_0 = \pm 3\hbar\gamma^2/8\pi r_{12}^3 = \pm\Delta_p/2$.

Not only can useful geometrical information be obtained from a spectrum of isolated pairs (Figure 1), but also a description of the dynamics. If the internuclear vector r_{12} is assumed to execute a hindered rotational motion reorienting about a fixed direction in space by random jumps between several positions, the changes in the spectrum shown in Figure 1 can be accurately predicted from the postulated dynamical model for the motion.⁶ Moreover, if the reorientation rate is fast compared with $\delta\nu_p$ [equation (3)], a simple average of $P_2(\cos\theta_{12})$ can be performed in order to determine the changes in the spectrum corresponding to this fast motional regime. If the fixed polar angle of B_0 relative to the reorientation axis is denoted by Γ , and the constant angle between r_{12} and the reorientation axis is denoted by ψ_{12} , the addition theorem for spherical harmonics

Figure 1 Spectrum of randomly oriented isolated pairs of dipolar-coupled spin- $\frac{1}{2}$ nuclei. The frequency separation between the singularities in the distribution of Pake doublets has the value $\Delta_p = 3\gamma^2\hbar/4\pi r_{12}^3$

can be used to perform the average $\langle P_2(\cos \theta_{12}) \rangle$ over the time-dependent azimuthal angle associated with $\mathbf{r}_{12}$, yielding⁷

$$\langle P_2(\cos \theta_{12}) \rangle = P_2(\cos \Gamma)(3 \cos^2 \psi_{12} - 1)/2 \quad (4)$$

Equation (4) is valid in the fast motion limit, for hindered rotation between positions of three-fold or higher symmetry, regardless of the details of the motion.

One concludes from equations (3) and (4) that the spectrum corresponding to random directions of the reorientation axis remains identical to the rigid case (Figure 1), but its width can be seen from equation (4) to be reduced by the factor $(3 \cos^2 \psi_{12} - 1)/2$.

3 SUPPRESSION OF OTHER BROADENING INTERACTIONS

In order to use dipolar spectra of isolated pairs as a structural tool, one needs to suppress other couplings. For spin- $\frac{1}{2}$ nuclei, heteronuclear dipole–dipole interactions, broadening by anisotropic chemical shifts or Knight shifts, and susceptibility broadening in small metallic particles, are among the most frequently found interactions that can mask the spectrum of dipole–dipole coupled isolated pairs.

3.1 Coherent Averaging

As a first step, the choice of an appropriate sequence of pulses for suppressing these couplings without affecting the homonuclear dipolar interactions is worth examining within the framework of average Hamiltonian theory.⁸ For δ function excitation pulses, the evolution of the density operator in the rotating frame in the limit of closely spaced pulses has been shown to be governed, after many cycles, by an average Hamiltonian:

$$\hat{\mathcal{H}} = (1/T) \sum_{k=1}^n \hat{\mathcal{H}}_{nk} \tau_k \quad (5)$$

where τ_k represents the time interval between the k th and the $(k + 1)$ th pulse in a cycle consisting of n pulses with period $T = \sum_{k=1}^n \tau_k$. The $\hat{\mathcal{H}}_{nk}$ values in equation (5) can be controlled by the experimenter by a suitable choice of pulses, adequate to the particular internal interactions present.

For the Carr–Purcell sequence, one has $n = 2$ and $\tau_1 = \tau_2 = 2\tau$. Representing the π pulses by the spin rotation operators $\hat{P}_1 = \hat{P}_2 = \exp(-i\pi \hat{I}_y)$ it can be shown⁸ that the average Hamiltonian reduces to:

$$\hat{\mathcal{H}} = \frac{1}{2}(\hat{\mathcal{H}} + \hat{P}_2 \hat{\mathcal{H}} \hat{P}_2^{-1}) \quad (6)$$

which satisfies the requirements for dipolar spectroscopy. Terms in $\hat{\mathcal{H}}$ corresponding to various types of shifts have the general form:

$$\hat{\mathcal{H}}_S = \sum_i \Delta\sigma_i \hat{I}_{zi} \quad (7)$$

where, for the case of secular chemical shifts, the shielding anisotropy $\Delta\sigma_i$ terms depend upon the orientation of the principal axes of the shielding tensor⁸ at the i th site relative to $\mathbf{B}_0$. From equation (7) it is clear that $\hat{\mathcal{H}}_S = 0$, since the π pulses represented by $\hat{P}_2$ in the second term of the equation simply change the sign of $\hat{\mathcal{H}}_S$. On the other hand, the homonuclear dipolar interaction [equation (1)], being bilinear in the individual spin operators, remains unaffected.

Although the secular heteronuclear interaction is also linear in the individual $\hat{I}_{zi}$ operators and can also be suppressed by the Carr–Purcell sequence and its variations, it is generally more convenient in practice to use strong rf irradiation at the Larmor frequency of these spins for an effective decoupling from the resonant nuclei.

Other pulse sequences also satisfy the requirements for dipolar spectroscopy. For example, several variations of the Carr–Purcell sequence have been proposed in order to compensate for the cumulative error caused by imperfect π pulses. In the Carr–Purcell–Meiboom–Gill (CPMG) sequence⁹ this is achieved by a 90° shift between the phase of the π pulses and the phase of the preparation pulse. Other compensated sequences, which have been proposed¹⁰ with a similar aim, involve cycles for 4, 8, or 16 π pulses.

3.2 Transient Nutations

A different approach is needed in order to examine the applicability of transient nutation as a tool for dipolar spectroscopy. This approach permits, at the same time, an evaluation of the effect of π pulses of finite width on dipolar spectra obtained using the CPMG sequence. In the laboratory frame, the total Hamiltonian $\hat{\mathcal{H}}$ includes, in addition to the Zeeman interaction $\hat{\mathcal{H}}_Z$, an interaction with a time-dependent rf field at resonance which may be amplitude modulated by pulses. It also includes a distribution of shifts [equation (7)] and the secular homonuclear dipole–dipole couplings $\hat{\mathcal{H}}_d$:

$$\hat{\mathcal{H}} = -\hbar\omega_0\hat{I}_z - 2\hbar\omega_1(t)\hat{I}_x \cos \omega_0 t - 2t\omega_1(t)I_x \cos \omega_0 t + \sum_i \Delta\sigma_i \hat{I}_{zi} + \hat{\mathcal{H}}_d \quad (8)$$

where, from equations (1) and (2),

$$\hat{\mathcal{H}}_d = \sum_{i,j} A_{ij} (\hat{I}_i \cdot \hat{I}_j - 3\hat{I}_{zi} \hat{I}_{zj}) \quad (9)$$

In the transient nutation experiment, an oscillating rf field of constant amplitude $2\omega_1/\gamma$ is applied suddenly along the x axis of the laboratory frame starting from equilibrium. The ensuing transient precession about the effective field in the rotating frame is then recorded, either point by point after an rf field of variable duration or by sampling through appropriately chosen receiver windows, and Fourier transformed. For simplicity, the conditions for decoupling of the nonresonant spins are assumed to hold, and consequently heteronuclear dipolar interactions have not been included in $\hat{\mathcal{H}}$.

One is interested in the evolution of the density operator $\hat{\rho}'$, in a rotating tilted frame,¹¹ where one of the two rotating components of the oscillating magnetic field is stationary along the z axis. The transformed density operator $\hat{\rho}'$ can be obtained from the laboratory frame operator $\hat{\rho}$ through the transformation $\hat{\rho}' = \hat{P}\hat{R}\hat{\rho}\hat{R}^{-1}\hat{P}^{-1}$ where

$$\hat{P} = \exp(i\pi\hat{I}_y/2); \quad \hat{R} = \exp(i\omega_0 t \hat{I}_z) \quad (10)$$

Starting from the time evolution of the density operator in the laboratory frame, the evolution of $\hat{\rho}'$ can be shown¹¹ to be governed by an effective Hamiltonian

$$\hat{\mathcal{H}}'_e = \hat{P}\hat{R}\hat{\mathcal{H}}_e\hat{R}^{-1}\hat{P}^{-1} \quad (11)$$

where $\hat{\mathcal{H}}_e = \hat{\mathcal{H}} - \hat{\mathcal{H}}_Z$, and $\hat{\mathcal{H}}_Z = -\hbar\omega_0\hat{I}_z$ denotes the Zeeman interaction.

Since the secular interactions in $\hat{\mathcal{H}}$ [equations (8) and (9)] commute with $\hat{R}$, the calculation of $\hat{\mathcal{H}}'_e$ from equations (10) and (11) is simplified. Neglecting terms oscillating at frequency $2\omega_0$, the effective Hamiltonian in the rotating tilted frame reduces to

$$\begin{aligned} \hat{\mathcal{H}}'_e = & -\hbar\omega_1\hat{I}_z + \sum_{i,j} A_{ij} (\hat{I}_i \cdot \hat{I}_j - 3\hat{I}_{xi} \hat{I}_{xj}) \\ & - \sum_i \Delta\sigma_i \hat{I}_{xi} \end{aligned} \quad (12)$$

Furthermore, if the amplitude of the rotating magnetic field ω_1/γ is large compared to the strength of the internal fields, and the system is initially in a state described by an equilibrium density operator $\hat{\rho}(0) = \text{const} \times \hat{I}_z$ in the laboratory frame [and hence by $\hat{\rho}'(0) = -\text{const} \times \hat{I}_x$ in the rotating tilted frame], the decay of the transient nutation signal is governed by the terms in equation (13) which commute with $\hat{I}_z$. It is therefore convenient to write, with the help of raising and lowering operators, the last two terms in equation (12) as a purely secular part, obeying the selection rule⁴ $\Delta(m_i + m_j) = 0$, plus nonsecular terms satisfying $\Delta(m_i + m_j) \neq 0$. This leads to:

$$\begin{aligned} \hat{\mathcal{H}}'_e = & -\hbar\omega_1\hat{I}_z - \frac{1}{2}\hat{\mathcal{H}}_d - \frac{3}{4} \sum_{i,j} A_{ij} (\hat{I}_{i+} \hat{I}_{j+} + \hat{I}_{i-} \hat{I}_{j-}) \\ & - \frac{1}{2} \sum_i \Delta\sigma_i (\hat{I}_{i+} + \hat{I}_{i-}) \end{aligned} \quad (13)$$

Equation (13) shows that the transient nutation signal satisfies the requirements for dipolar spectroscopy. Since the last two terms have become nonsecular and do not contribute to the decay, inhomogeneous broadening caused by resonance shifts is suppressed, although an inhomogeneous rf field may still cause broadening.¹² In addition, the strength of the secular dipolar term in equation (14) is one-half the value of the dipolar interaction in the laboratory frame¹³ [equation (9)]. Hence the width of the spectrum of isolated pairs shown in Figure 1 is expected to be half the value calculated from equation (3).

3.3 CPMG Sequence with Finite Pulse Widths

The system is prepared by an initial $\pi/2$ pulse and evolves during a time interval τ . A train of π pulses of width t_w , separated by intervals 2τ , and phase shifted by 90° with respect to the initial $\pi/2$ pulse is then applied. The signal amplitudes at the echo maxima are further recorded as a function of time, and Fourier transformed to obtain the frequency spectrum.

Since for the CPMG case, $\omega_1(t)$ in equation (8) represents a periodic function of period $T = 2\tau + t_w$ consisting of rectangular pulses with amplitudes $\omega_{1a} = \pi/t_w$, the steps leading from equation (8) to equation (13) yield an effective Hamiltonian identical to $\hat{\mathcal{H}}'_e$ [equation (13)], but with a time-dependent term $\hbar\omega_1(t)\hat{I}_z$. Moreover, since one is observing the evolution stroboscopically, it is convenient to transform $\hat{\mathcal{H}}'_e$ to a ‘toggling frame’ where the precession about externally

applied fields, either static or time-dependent, is removed. This is achieved by the transformation¹¹

$$\hat{\rho}'_{\text{et}}(t) = \exp[-i\phi(t)\hat{I}_z/2] \hat{\rho}'_{\text{e}}(t) \exp[i\phi(t)\hat{I}_z/2] \quad (14)$$

where:

$$\phi(t) = 2 \int_0^t \omega_1(t') dt' \quad (15)$$

The evolution of $\hat{\rho}'_{\text{et}}(t)$, given by equations (14) and (15), is governed by the effective Hamiltonian

$$\begin{aligned} \hat{\mathcal{H}}'_{\text{et}} = & -\frac{1}{2}\hat{\mathcal{H}}_{\text{d}} - \frac{3}{4} \sum_{i,j} A_{ij} \{ \hat{I}_{i+} \hat{I}_{j+} \exp[i\phi(t)] + \text{c.c.} \} \\ & - \frac{1}{2} \sum_i \Delta \sigma_i \{ \hat{I}_{i+} \exp[-i\phi(t)/2] + \text{c.c.} \} \end{aligned} \quad (16)$$

where c.c. denotes the Hermitian conjugate of the operators within the braces.

As pointed out by Waugh and Wang,¹¹ only the zero-frequency components of the time-dependent terms in equation (16) can contribute to the observed decay, because the time-dependent parts correspond to frequencies much higher than A_{ij} and $\Delta \sigma_i$ if $1/(t_w + 2\tau)$ is sufficiently large. For the periodic functions in equation (16), which involve sine and cosine functions of $\phi(t)$ and $\phi(t)/2$, the zero-frequency components can be obtained graphically in a relatively simple manner by calculating the corresponding averages over one period. Assuming the first π pulse at time from τ from the origin and a sequence of perfect rectangular π pulses of width t_w , the zero-frequency component of $\exp[\pm i\phi(t)/2]$ can be seen to vanish leading to a suppression of shifts in equation (16). On the other hand, the dc component of $\exp[i\phi(t)]$, denoted by $\mathcal{L}$, is given by³

$$\mathcal{L} = \frac{1}{T} \int_0^T \cos \phi(t') dt' = 1 - D \quad (17)$$

where $T = 2\tau + t_w$ is the period, and $D = 2\tau/T$ denotes the duty factor of the sequence of π pulses.

In order to evaluate the effect of π pulses of finite width upon the spectrum of isolated pairs (Figure 1), one can diagonalize the static part of $\hat{\mathcal{H}}'_{\text{et}}$ [equation (16)] given by

$$\begin{aligned} \hat{\mathcal{H}}'_{\text{et}} = & -\frac{1}{2}A_{12}(\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2 - 3\hat{I}_{z1}\hat{I}_{z2}) - \frac{3}{4}A_{12}(\hat{I}_{1+}\hat{I}_{2+} + \hat{I}_{1-}\hat{I}_{2-}) \\ & + \hat{I}_{1-}\hat{I}_{2-}\mathcal{L}^* \end{aligned} \quad (18)$$

For spin- $\frac{1}{2}$ nuclei, an adequate basis is composed of the singlet and triplet states introduced earlier in connection with equations (1) and (2). The states $|t_0\rangle$ and $|s_0\rangle$ are still eigenfunctions of $\hat{\mathcal{H}}'_{\text{et}}$, whereas two appropriate linear combinations of $|t_+\rangle$ and $|t_-\rangle$ constitute the other two eigenstates.

The quantity of interest in the CPMG experiment is proportional to $\text{Tr}(\hat{\rho}'_{\text{et}}(t)\hat{I}_z)$ and can be explicitly computed³ from the known eigenvalues and eigenvectors yielding a spectrum of two lines for a given orientation of $\mathbf{B}_0$. The frequency separation Δ between the lines for $\theta_{12} = \pi/2$, corresponding to the singularities in the spectrum of randomly oriented pairs

(Figure 1) is governed by the second term in equation (18), since the first term commutes with $\hat{\rho}'_{\text{et}}(0) = \text{const} \times \hat{I}_z$ and does not cause any decay. It can be shown³ that Δ is given by

$$\Delta = 3\gamma^2\hbar(1 - D)/4\pi r_{12}^3 \quad (19)$$

4 DIPOLAR SPECTRA

Figure 2 shows a ^{13}C spectrum of polycrystalline acetic acid at $T = 80\text{ K}$; there is a very close correspondence with the theoretical spectrum shown in Figure 1. The sample contains 4% doubly ^{13}C -labeled acetic acid dissolved in ^{13}C -depleted acetic acid. A modified CPMG sequence with $2\tau = 86.4\ \mu\text{s}$ and $t_w = 9.6\ \mu\text{s}$, including proton decoupling and cross polarization,¹⁴ was employed. A central peak partially caused by spin locking⁷ in the average rf field is omitted for clarity.

Dipolar spectra obtained by employing transient nutations generally display poorer resolution than do those obtained with CPMG sequences, because of the reduction in spectral range by a factor of 2 [equation (13)]. Good resolution is especially important when pairs with more than one interatomic distance are involved.¹⁵ On the other hand, for the CPMG sequence, the splitting Δ (Figure 2) depends on the duty factor, but

Figure 2 ^{13}C spectrum of polycrystalline acetic acid at $T = 80\text{ K}$. The sample contains 4% doubly ^{13}C -labeled acetic acid dissolved in ^{13}C -depleted acetic acid. A modified CPMG sequence with pulse separation $2\tau = 86.4\ \mu\text{s}$ and pulse width $t_w = 9.6\ \mu\text{s}$ was employed (Reproduced by permission from M. Engelsberg and C. S. Yannoni, *J. Magn. Reson.*, 1990, **88**, 393)

Figure 3 ^{13}C dipolar spectra of benzene ($1,2\text{-}^{13}\text{C}_2$) chemisorbed on $\text{Pt}/\eta\text{-Al}_2\text{O}_3$ obtained by a modified CPMG sequence at various temperatures. The narrow central peak, partially due to spin locking, has been omitted for clarity in all spectra, except the one at 125 K. (Inset) Conventional (FT of FID) proton-decoupled spectrum in the same system at $T = 80\text{ K}$, with shifts measured with respect to a TMS reference (Reproduced by permission from M. Engelsberg, C. S. Yannoni, M. A. Jacintha, C. Dybowski, and R. E. de Souza, *J. Phys. Chem.*, 1994, **98**, 2397. © 1994 American Chemical Society)

the variation has been shown experimentally³ to agree with the linear dependence predicted by equation (19). Thus a simple correction permits accurate measurement of interatomic distances.³

One example of dipolar spectroscopy which helps to illustrate its applicability is provided by the study of benzene chemisorbed on an η -alumina-supported platinum catalyst.⁶ The inset in Figure 3 shows a conventional proton-decoupled ^{13}C spectrum of benzene ($\nu_0 = 15\text{ MHz}$), doubly labeled in *ortho* positions, chemisorbed on $\text{Pt}/\eta\text{-Al}_2\text{O}_3$ at $T = 80\text{ K}$, obtained by FT of the FID. Also shown in Figure 3 are spectra of the same system at various temperatures obtained from a modified CPMG sequence, where the suppression of inhomogeneous broadening uncovers a rich variety of geometrical and dynamical information. The four peaks at the lowest temperature correspond to benzene molecules at different sites, not to different bond lengths.^{6,16} For some sites

the molecules are rapidly reorienting about the hexad axis,¹⁷ corresponding to $\psi_{12} = \pi/2$ in equation (4), while for others this reorientation rate is small. This explains the difference of a factor of 2 in the splittings of the two inner peaks compared with the outer peaks. At temperatures above 80 K, the spectra can be simulated⁶ assuming that the axis of hindered rotation no longer remains perpendicular to the plane of the molecule.

Other examples^{15,18,19} of dipolar spectra in a variety of systems further illustrate the usefulness of the techniques described in Section 3 for probing the structure and dynamics of solids.

1 INTRODUCTION

Double quantum coherence, a dipole-forbidden degree of freedom in a multilevel spin system, is an important feature of many time domain techniques. Connecting a pair of states where the Zeeman quantum numbers differ by ± 2 , a coherent two quantum superposition is the simplest manifestation of the general phenomenon of multiple quantum coherence. Already, however, it exhibits the same phase properties and time development characteristic of more complicated modes, and it serves as an indispensable building block for both theoretical and experimental purposes. Double quantum and related nondipole coherences often provide the mechanism by which modern multidimensional pulse sequences operate.¹⁻⁹

Magnetic resonance is about oscillations, particularly those of a time-dependent magnetization as picked up by a receiving coil. The most basic picture, exemplified best by a collection of uncoupled spin- $\frac{1}{2}$ nuclei, is of a magnetization vector precessing about an applied field with a given amplitude, frequency, and phase. The amplitude of the vector is, of course, its length, from which the strength of the signal is derived. Frequency indicates the number of revolutions completed each second, while the phase denotes the degree of advancement within a cycle. It is phase—where the magnetization is at any point, and not its length or angular velocity—that is the key to coherence, and it is coherence that makes time domain NMR possible.

Consider first the physical meaning of single quantum coherence, which underpins the usual model of transverse magnetization. For an ensemble of identical, noninteracting spin- $\frac{1}{2}$ nuclei, we picture a set of independent oscillators each precessing with the same frequency and amplitude (Figure 1). The net magnetization, which arises as the sum of these separate contributions, is determined entirely by the phase relationships among the different vectors. In an array where the phases are randomly distributed between 0 and 2π , as in Figure 1(a), the transverse components vanish owing to destructive interference. There remains only a time-independent longitudinal component along the field. This *absence* of phase coherence is the normal condition for a spin system in thermal equilibrium. *Coherent* oscillations, by contrast, develop following a $\pi/2$ pulse, which acts to synchronize the phases of all the vectors [Figure 1(b)].

Figure 1 (a) Incoherent and (b) coherent phase relationships in an ensemble of two-level systems

Everything moves together, and a net magnetization is detected in the plane perpendicular to the field.

Viewed as a collection of oscillators, the spin- $\frac{1}{2}$ system thus exhibits coherence when all its component vectors precess with the same phase. Quantum mechanically, one describes the state as a *coherent superposition* (or linear combination) of the spin-up and spin-down states— $|\alpha\rangle$ and $|\beta\rangle$ —for which the difference in Zeeman quantum numbers ($\frac{1}{2}$, $-\frac{1}{2}$) is one unit. The phase of precession appears as a phase in the wavefunction, and in this way the physical picture of magnetization is translated into a more abstract, yet more general concept of single quantum coherence. The same quantum mechanical interpretation of phase coherence can

then be extended, by analogy, to double quantum coherence and beyond, for which the simpler model of magnetization does not apply.

2 VECTOR PRECESSION MODEL AND COHERENCE

Any quantitative understanding of quantum mechanical coherence begins with an ensemble of two-level systems evolving under some Hamiltonian $\hat{H}$. Let the two possible states, denoted as $|1\rangle$ and $|2\rangle$, be left unspecified for now, although presently we will associate them with spins. By taking a general approach to coherence at least initially, we are reminded that the concept is not restricted to NMR. Many of the same ideas find application in microwave and electron paramagnetic resonance (EPR) spectroscopy, as well as certain optical phenomena.

Thus understood, each individual wavefunction

$$|\psi\rangle = c_1|1\rangle + c_2|2\rangle \quad (1)$$

may be reorganized into a density operator $\hat{\rho}$ whose three linearly independent and orthogonal components form a vector in a three-dimensional Liouville space:

$$\rho_x = c_1c_2^* + c_1^*c_2 \quad (2a)$$

$$\rho_y = -i(c_1c_2^* - c_1^*c_2) \quad (2b)$$

$$\rho_z = c_1^*c_1 - c_2^*c_2 \quad (2c)$$

These quantities are just numerical representations of the basis operators

$$\hat{\rho}_x = |1\rangle\langle 2| + |2\rangle\langle 1| \quad (3a)$$

$$\hat{\rho}_y = -i(|1\rangle\langle 2| - |2\rangle\langle 1|) \quad (3b)$$

$$\hat{\rho}_z = |1\rangle\langle 1| - |2\rangle\langle 2| \quad (3c)$$

used by Pauli to describe electron spin. A fourth component ($c_1c_1^* + c_2c_2^* = 1$) merely restates the normalization condition, and is of no further interest.

If the Hamiltonian matrix elements $H_{rs} = \langle r|\hat{H}|s\rangle$ are similarly combined into the vector

$$\Omega_x = H_{12} + H_{21} \quad (4a)$$

$$\Omega_y = -i(H_{12} - H_{21}) \quad (4b)$$

$$\Omega_z = H_{11} - H_{22} \quad (4c)$$

then the time-dependent Schrödinger equation can be recast into a precession equation,

$$\frac{d\rho}{dt} = \rho \times \Omega \quad (5)$$

The density vector ρ thus precesses about Ω in analogy to the precession of a spin- $\frac{1}{2}$ magnetization about an applied field.¹⁰ This motion is made explicit when ρ_x and ρ_y are combined into a single transverse component, $\rho_{xy} = \rho_x + i\rho_y$, to give

$$\frac{d\rho_{xy}}{dt} = -i\Omega_z\rho_{xy} \quad (6)$$

and thence

$$\rho_{xy}(t) = \rho_{xy}(0) \exp(-i\Omega_z t) \quad (7)$$

The longitudinal population, ρ_z , remains constant.

Nothing has happened so far, for we have only *rearranged* the Schrödinger equation for one spin. The vector cross-product form in equation (5) is recognized instantly as the Bloch equations in the absence of relaxation, and no new features have yet appeared.

The notion of coherence enters now through the *phase* of precession, which is related to the coefficients in the original two-state superpositions. Writing each complex coefficient c_j as

$$c_j = |c_j| \exp(i\phi_j) \quad (8)$$

we have [using equations (2a) and (2b)]

$$\rho_{xy}(t) = 2|c_1||c_2| \exp[-i(\Omega_z t + \Delta\phi)] \quad (9)$$

for which the phase is established by $\Delta\phi = \phi_2 - \phi_1$. Since each wavefunction may exhibit a different value of $\Delta\phi$, phase coherence is determined by the extent to which the individual precessional motions are correlated throughout the ensemble. The proper relationships appear when the ρ vectors are averaged over the ensemble to yield a statistical description of the mixed state.^{1,11,12}

The two extreme cases discussed above now appear in more quantitative form:

1. *No coherence*, or random phases as in Figure 1(a). Here the mixed states is an incoherent superposition of the two basis states, with the population difference given by the time-dependent z component $|c_1|^2 - |c_2|^2$. For spins $\frac{1}{2}$, the situation corresponds to thermal equilibrium.
2. *Full transverse coherence*. The populations $|c_1|^2$ and $|c_2|^2$ become equal, and the phases $\Delta\phi$ are uniform across the ensemble. All vectors precess synchronously in the xy plane, as already illustrated in Figure 1(b).

For the prototype example of a spin- $\frac{1}{2}$ nucleus, the ensemble-averaged vector ρ is isomorphic to the physical magnetization. Its z component is proportional to the population difference, whereas the x and y components correspond to the transverse magnetization in the rotating frame. We need simply take $\hat{I} = \frac{1}{2}\hat{\rho}$ to recover the usual angular momentum operators,

$$\hat{I}_x = \frac{1}{2}(|\alpha\rangle\langle\beta| + |\beta\rangle\langle\alpha|) \quad (10a)$$

$$\hat{I}_y = -\frac{i}{2}(|\alpha\rangle\langle\beta| - |\beta\rangle\langle\alpha|) \quad (10b)$$

$$\hat{I}_z = \frac{1}{2}(|\alpha\rangle\langle\alpha| - |\beta\rangle\langle\beta|) \quad (10c)$$

and thus appreciate the one-to-one correspondence. The real power of the vector precession model, however, only becomes apparent in *multilevel* spin systems, where the underlying physical picture is less readily apprehended. Here the wavefunctions are generalized to

$$|\psi\rangle = c_1|1\rangle + c_2|2\rangle + \dots + c_N|N\rangle \quad (11)$$

so the density operator $|\psi\rangle\langle\psi|$ now contains N^2 elements of the form $|r\rangle\langle s|$, instead of the four elements found in the two-level case. Nevertheless, for any pair of levels r and s we can form pseudospin operators analogous to those in equation (10),

$$\hat{I}_x^{r-s} = \frac{1}{2}(|r\rangle\langle s| + |s\rangle\langle r|) \quad (12a)$$

$$\hat{I}_y^{r-s} = -\frac{i}{2}(|r\rangle\langle s| - |s\rangle\langle r|) \quad (12b)$$

$$\hat{I}_z^{r-s} = \frac{1}{2}(|r\rangle\langle r| - |s\rangle\langle s|) \quad (12c)$$

and thereby re-establish contact with the vector precession model. These fictitious spin- $\frac{1}{2}$ operators form a basis for the density operator of an arbitrary N -level spin system.^{13–15} They permit one to treat a transition between *any* two states $|r\rangle$ and $|s\rangle$ using the same physical picture as for spin $\frac{1}{2}$. The x and y components describe the phase coherence, and the z component again supplies the population difference between the two states. And with each state $|r\rangle$ understood to be a Zeeman eigenstate having z component equal to m_r ,

$$\hat{I}_z|r\rangle = m_r|r\rangle \quad (13)$$

there is no restriction on the order of coherence, $k = m_r - m_s$. The multiple quantum coherence is just the physical manifestation of a uniform phase relationship between states $|r\rangle$ and $|s\rangle$, deriving from the particular linear combinations specified by c_r and c_s .

Two spin- $\frac{1}{2}$ nuclei, for instance, may be described by four direct-product states— $|1\rangle = |\alpha\alpha\rangle$, $|2\rangle = |\beta\alpha\rangle$, $|3\rangle = |\alpha\beta\rangle$, $|4\rangle = |\beta\beta\rangle$ —out of which a set of fictitious spin- $\frac{1}{2}$ operators can be constructed according to equation (12). Double quantum coherence, corresponding to coherent superposition of $|\alpha\alpha\rangle$ and $|\beta\beta\rangle$, is then represented by the operators $\hat{I}_x^{1-4}$ and $\hat{I}_y^{1-4}$, while the population difference between the $\alpha\alpha(m = 1)$ and $\beta\beta(m = -1)$ states is given by $\hat{I}_z^{1-4}$. The three fictitious spin- $\frac{1}{2}$ operators commute as angular momenta within the 1–4 double quantum subspace, and consequently the well-understood properties of three-dimensional rotations fully apply.

The fictitious spin- $\frac{1}{2}$ operators, along with equivalent representations such as the product operator basis, thus bring out a fundamental characteristic of all complex spin systems: there exist *orthogonal modes of coherence*,¹⁶ analogous to the normal modes of other spectroscopic methods, which can be excited individually and monitored dynamically. These independent degrees of freedom are the irreducible units from which complex assemblies of spins are formed. Each mode is a coherent superposition of a certain order, rendered graphically as an independent vector precessing in an abstract three-dimensional space. With frequency-selective excitation, for example, a spectroscopist can address a particular pair of levels within the large system and interact with it as a spin $\frac{1}{2}$. The usual resonant phenomena associated with spin- $\frac{1}{2}$ nuclei— $\pi/2$ pulses, formation of coherence, evolution under chemical shifts and spin–spin couplings, relaxation, and so forth—have transparent analogies within the two-level subspace, as suggested in Figure 2.

Figure 2 Isolation of two states in a multilevel system

3 PROPERTIES OF DOUBLE QUANTUM COHERENCE

The minimum configuration needed to sustain double quantum coherence is provided by the three levels of a spin-1 nucleus (Figure 3). Here the Zeeman states typically are perturbed by an electric quadrupole coupling, whereby the nonspherical charge distribution of the nucleus interacts with the electric field gradient of the surrounding electrons. This interaction, characterized by a quadrupolar coupling constant ω_Q , shifts the $m = 1$ level by $-\frac{1}{3}\omega_Q$, the $m = 0$ level by

Figure 3 Spin-1 energy levels in the presence and absence of an electric quadrupole coupling. Only the single quantum transitions (and not the double quantum) are split by the quadrupolar interaction

$\frac{2}{3}\omega_Q$, and the $m = -1$ level by $-\frac{1}{3}\omega_Q$ relative to the Larmor frequency ω_0 . Single quantum transitions corresponding to $(1, 0)$ and $(0, -1)$ consequently appear at $\omega_0 \pm \omega_Q$, often resulting in a broad spectrum difficult to measure when ω_Q is large.

The double quantum transition $(1, -1)$, however, remains unaffected by the quadrupolar coupling, and resonates at $2\omega_0$. When prepared as a coherent superposition, it evolves independently of the quadrupolar Hamiltonian, and develops instead only under the influence of smaller internal interactions such as chemical shifts and spin-spin couplings. Further, the double quantum coherence displays two essential spectral properties: (1) it precesses in the rotating frame at exactly twice the resonant offset of a single quantum transition; (2) its phase (understood to be the instantaneous position of the transverse vector ρ_{xy} in an abstract double quantum space) is shifted by 2ϕ in response to a shift in radiofrequency phase by ϕ .

These key aspects of the double quantum response, when generalized to k quantum coherence ($2\Delta\omega \rightarrow k\Delta\omega$, $2\phi \rightarrow k\phi$), are exploited in numerous spectroscopic techniques. Among the most important are those designed to separate signals with different orders of coherence, and to excite or detect signals from different orders selectively. The method of time proportional phase incrementation, for example, is rooted in the $n\phi$ phase behavior of double quantum coherence, which was originally observed for double quantum coherence in a three-level system.

A third property, of critical importance experimentally, is ‘invisibility’. Single quantum coherence is detectable as ordinary magnetization precisely because it exhibits a nonvanishing magnetic dipole moment. The dipole receiver records the oscillations of $\langle \hat{I}_x \rangle$ and $\langle \hat{I}_y \rangle$ which are nonzero only between states where $\Delta m = \pm 1$. But double quantum coherence, which connects Zeeman states with $\Delta m = \pm 2$, generates no such observable magnetization and therefore must be detected indirectly.

Cast in general spectroscopic terms, the idea is to monitor a forbidden transition through its effect on an allowed transition. Indirect schemes are by no means limited to NMR, and indeed one of the earliest demonstrations involved the detection, by optical techniques, of coherent microwave effects exhibited by molecules in excited triplet states.¹⁷ Coherence between the electron spin levels, although not directly observable owing to symmetry restrictions, nevertheless was measured through changes in phosphorescence. The optical transitions are coupled to the magnetic sublevels of the triplet, and a striking modulation develops when resonant microwave pulses are applied to the electron spins. Electron free precession and electron spin echoes, normally ‘hidden’ from view, were observed in this way, and the indirect detection of double quantum coherence soon followed.¹⁸

NMR pulse sequences for indirect detection are generally designed with four distinct periods:

1. *Excitation* of the double quantum coherence, by which a suitable nonequilibrium state is prepared.
2. *Evolution* of the coherence in the presence of natural or externally manipulated couplings and local fields. During this period, the double quantum coherence responds to its environment and oscillates at its characteristic spectral frequencies.
3. *Conversion* of the coherence from an unobservable double quantum form to ordinary single quantum magnetization.

4. *Detection* of the newly created single quantum coherence using ordinary means.

In the usual procedure, one halts the evolution of the double quantum coherence after a specified interval, converts it to an observable single quantum mode, and then records a free induction decay. The first point of the free induction signal, however, depends on the prior history of the double quantum coherence, and thus the progress of the hidden mode is reflected in the observable spectrum. An entire double quantum ‘interferogram’ can be mapped out in this way, point by point, through systematic incrementation of the evolutionary period. Fourier transformation of the interferogram reveals the spectral response of the double quantum mode to the surrounding local fields. The procedure clearly is the same as for two-dimensional spectroscopy,¹⁹ and in some ways the indirect detection of double quantum spectra in the mid-1970s was a precursor of two-dimensional NMR.

All these properties and considerations pertain to systems of coupled spins as well, the simplest being two spin- $\frac{1}{2}$ nuclei linked by a dipolar or J interaction (Figure 4). The double quantum transition is again between states with $m = \pm 1$, existing now as the direct products $|\alpha\alpha\rangle$ and $|\beta\beta\rangle$. The coherence, as before, evolves independently of the coupling between the two outermost levels. In this system, though, it is the spin-spin interaction that is removed from the dynamics, rather than the analogous quadrupolar coupling. The phase shifts too are enhanced by the expected factor of 2.

Double quantum coherence is the maximum that can be supported between two spin- $\frac{1}{2}$ nuclei. As the *total spin coherence*, it is exemplary of the more complex collective modes from which large coupling networks are built. Consider, in this context, the two spins to constitute a closed system, and picture first a *single quantum* coherence as arising from just one of the spins alone, say ‘A’. The transverse magnetization of A then precesses coherently in the local field produced by spin B, which we assume to have magnitude J . Now spin B, roughly speaking, may be up or down, and therefore the A coherence responds to two possible local field configurations: J and $-J$. The single quantum spectrum shows, accordingly, resonances at the two frequencies. But the double quantum coherence, which demands the active participation of *both* spins, is left with no local field to which it can respond. Both spins are tied up in the formation of the coherent superposition, and so the double quantum mode can only evolve as if no spin-spin coupling exists.

In general, collective modes of coherence involve n active spins (which ‘flip’) and q passive spins (which ‘watch’). The order of coherence is established by the Zeeman quantum numbers of the active participants, while the local field is determined by the remaining passive spins. The spectrum of

Figure 4 Energy levels for a pair of weakly coupled spin- $\frac{1}{2}$ nuclei

Figure 5 Proton multiple quantum spectra ($|k| = 1, 2, \dots, 6$) for benzene in an anisotropic solvent. Preparation sequences are built around a two quantum propagator. (a) Nonselective excitation. There are 76 lines in the normal one quantum spectrum, but only two in the five quantum spectrum, and one in the six quantum spectrum. (b) Selective excitation of coherences for which $|k| = 0$ and $|k| = 4$. (Reproduced by permission of the American Institute of Physics from Warren et al.²⁰)

a multiple quantum coherence, which reflects all the algebraic combinations of the q passive spins, becomes progressively simpler as more spins are allowed to participate actively. The limit is reached with N -quantum coherence in an N -spin system, where the local field vanishes (except for combined chemical shifts and resonance offsets).

One of the early goals of multiple quantum NMR, in fact, was to simplify spectra obtained from oriented systems without sacrificing information about the coupling. A complete picture of the local fields frequently can be extracted from the few resonances available to a high-order coherence, whereas the equivalent single quantum spectrum remains an impenetrable tangle of lines.

Figure 5(a) illustrates how such simplification is brought about for the case of benzene partially oriented in a liquid crystal solvent. The hydrogen nuclei of each molecule constitute an isolated six-spin system from which multiple quantum signals of orders 1 through 6 can be elicited. The number of lines decreases dramatically with increasing order k , to the point where the six quantum spectrum shows only the one resonance characteristic of the total spin coherence.

Figure 5(b) demonstrates further that multiple quantum coherences can be excited selectively, the example here being primarily four quantum excitation. Selectivity is achieved by exploiting the phase properties of the coherences. Iterative excitation sequences, assembled by concatenating appropriately phase-shifted pulse cycles, are used to channel the coherence into the desired degrees of freedom.²⁰

Collective spin modes also form the basis for a number of spin *filtering* techniques. Often designed to exploit the total spin coherence, these methods can be used to select signals from clusters of various sizes—beginning with pairs. Double quantum coherence is the basis for one of the first successful

filtering schemes, the detection of ^{13}C – ^{13}C pairs at natural abundance (see Section 5).

4 DOUBLE QUANTUM EFFECTS IN QUADRUPOLEAR SYSTEMS

Experiments carried out in the early to mid-1970s demonstrated many of the properties of double quantum coherence in quadrupolar nuclei such as ^2H , ^{23}Na , and ^{27}Al . Frequency-selective excitation by narrowband, ‘soft’ pulses typically was used to interact with designated pairs of levels, creating circumstances well suited for treatment within the fictitious spin- $\frac{1}{2}$ formalism.

Some of the initial applications demonstrated how double quantum techniques could be used effectively to eliminate dominant quadrupolar or dipole–dipole interactions, while leaving intact smaller couplings of spectroscopic interest. As an alternative to multiple pulse coherent averaging sequences, for example, one might want to study the residual protons in a heavily deuterated material. If hydrogen–hydrogen dipolar interactions are sufficiently attenuated in the dilute system, then the underlying chemical shifts will become visible once the deuterium–hydrogen couplings are eliminated. Unfortunately a technical difficulty arises with conventional decoupling, since the radiofrequency amplitude ω_1 must greatly exceed a quadrupole coupling constant ω_Q of over 100 kHz. If, however, the abundant deuterium nuclei (I) are irradiated continuously with a *weak* radiofrequency field, then *double quantum* decoupling^{21–23} can proceed within the fictitious double quantum subspace spanned by the states $|m = 1\rangle$ and $|m = -1\rangle$. For soft irradiation at the deuterium Larmor frequency there is induced a continuous double quantum nutation at an effective angular velocity

$$\omega_e = \sqrt{(2D_{IS})^2 + (\omega_1^2/\omega_Q)^2} \quad (14)$$

where D_{IS} denotes the heteronuclear coupling constant. This latter term, off-resonance by D_{IS} , is accelerated to $2D_{IS}$ as described in Section 3. Rotated about the x axis in double quantum space (recall Figure 2), the dipolar interaction now averages to zero when ω_e exceeds D_{IS} , a condition much less stringent than the requirement that ω_1 cover the full width of the deuterium spectrum. Hence a radiofrequency amplitude of

$$\omega_1 \gg \sqrt{\omega_Q D_{IS}} \quad (15)$$

rather than $\omega_1 \gg \omega_Q$ suffices. With the $(1, -1)$ transition stirred continuously by the narrowband decoupling field, only the $|m = 0\rangle$ state (which exerts no z field on the S spin) is left.

A deuterium-decoupled chemical shift anisotropy powder pattern of the residual ^1H nuclei in deuterated ice, shown in Figure 6, illustrates the ability of the technique to improve the resolution of dilute proton systems in the solid state.^{22, 23} Effects of motion show up in the temperature-dependent powder patterns as well, with the lineshapes undergoing motional averaging characteristic of tetrahedral jumps. The behavior is consistent with the protons hopping around the four hydrogen bonds in the ice lattice.

Figure 6 (a) NMR spectra of residual protons in heavy ice (99% deuterium) at -90°C with and without deuterium decoupling. The chemical shift anisotropy of the hydrogen-bonded protons is approximately 34 ppm. (Reproduced by permission of the American Physical Society from Pines et al.^{22a}) (b) The spectra are motionally narrowed at higher temperatures, developing lineshapes consistent with tetrahedral jumps. (By courtesy of D. E. Wemmer)

Another use of double quantum excitation is to *bypass* the quadrupolar coupling itself, by looking directly at the unbroadened $(1, -1)$ transition. Narrowband excitation again is used to address only the double quantum subspace, within which the resonant nutation frequency is ω_1^2/ω_Q . The condition for a $\pi/2$ pulse is therefore

$$\frac{\omega_1^2 \tau_p}{\omega_Q} = \frac{\pi}{2} \quad (16)$$

for a burst of duration τ_p . Hence an effective $\pi/2$ pulse can be applied to convert a double quantum population difference into a double quantum transverse coherence. If the $m = 1, 0$, and -1 Zeeman states are designated as $|1\rangle$, $|2\rangle$, and $|3\rangle$, respectively, then the effect is to rotate $\hat{f}_z^{1-3}$ into $\hat{f}_x^{1-3}$. Once created, the 1–3 transverse coherence vector precesses in a local field due only to the chemical shift and is unaffected by the quadrupolar coupling. The response is mapped out point by point to obtain a double quantum interferogram in the manner discussed in Section 3.

An example of a quadrupole-free double quantum spectrum is provided in Figure 7, with both the time domain and Fourier transform shown.²³ The spectrum is of the chemical shift anisotropy of deuterium in benzene (a powder pattern only 6 ppm wide), obtained in the presence of a 100 kHz quadrupolar coupling constant. What the double quantum approach thus demonstrates is an ability to *avoid* rather than eliminate a large and obstructive coupling. Neither spatial nor spin averaging is employed in a frontal attack on the unwanted interaction, which is left untouched. A mode of coherence indifferent to the offending Hamiltonian is used instead.

Another application involves *spin locking*, by which the lifetime of a double quantum coherence is prolonged in the rotating frame. Analogous to conventional spin locking, the

Figure 7 (a) Double quantum free induction decay of deuterium in solid benzene- d_1 doped (10%) into benzene, detected indirectly. Signals were recorded at -40°C , with proton decoupling. (b) Fourier transform, revealing the chemical shift anisotropy. The left edge of the pattern corresponds to the field oriented along the benzene plane normal; the peak at the right corresponds to the perpendicular direction. (By courtesy of S. Vega)

idea is to align the coherence along an applied radiofrequency field. Thus a single quantum coherence parallel to, say, the x axis might be prepared by a $\pi/2$ pulse applied about the y axis of the rotating frame, whereupon the radiofrequency phase would be shifted by $\pi/2$ to realign the effective field along x . With ω_1 now on the x axis, the x magnetization is held fixed along the effective field and is relaxed primarily by lower-frequency motions comparable to ω_1 . The same treatment can be imposed on a *double quantum* coherence as well, provided that its nutation and phase characteristics are respected. First, the two quantum mode is aligned along the x axis by a soft pulse resonant only with the $(1, -1)$ transition. Second, the spin locking burst must be shifted by $\pi/4$ (rather than $\pi/2$) in keeping with the two-fold sensitivity to radiofrequency phase. The applied shift of $\pi/4$ is perceived by the double quantum coherence as $\pi/2$, and the spin lock is established.¹⁸

Figure 8 demonstrates the slow decay of a spin locked two quantum signal in deuterated benzene, where ordinarily the transverse relaxation time is only a few hundred microseconds. Held by the phase-shifted locking field, the coherence now endures for some milliseconds.

Spinor behavior and interferometric effects, too, have been observed in multilevel systems where selective excitation creates fictitious spin- $\frac{1}{2}$ characteristics. Simultaneous irradiation of all transition frequencies in a spin 1, for example, allows the

Figure 8 Double quantum phenomena observed for the carboxyl deuterons of crystalline oxalic acid dihydrate. The solid lines represent fits to theoretical models. (a) Free induction decay. A weak $\pi/2$ pulse ($\tau_p = 58 \mu\text{s}$) establishes double quantum coherence across the $(1, -1)$ transition. The coherence evolves undetected for a time τ before being converted to observable magnetization by the strong pulse at the end. (b) Under a spin locking pulse, shifted in phase by $\pi/4$, the double quantum coherence persists for a few milliseconds in the rotating frame. The requisite phase shift of $\pi/4$ (compared with $\pi/2$ in single quantum spin locking sequences) was an early indication that k -quantum coherences display k -fold sensitivity to phase shifts. (By courtesy of S. Vega)

particle to behave as a boson, with its state vector invariant to a rotation by 2π . Selection of just *one* pair of levels within a fictitious spin- $\frac{1}{2}$ subspace, however, creates a pseudofermion. Here the state vector changes sign under a rotation of 2π , going from $|\psi\rangle$ to $-|\psi\rangle$, and returning back to $|\psi\rangle$ only upon rotation by 4π . Detection of this antisymmetry requires interference with a reference state, since the negative sign is lost when the wavefunction is squared. A striking demonstration of spinor periodicity is offered in Figure 9.²⁴

Numerous other double quantum effects have been reported, including analogs of familiar NMR phenomena such as spin echoes, rotary echoes, rotary saturation, cross polarization, and population inversion.^{18,25,26} Many of these experiments also involve nonintegral spins, in which systems of more than three levels are manipulated. Both single pulse excitation and multistep transfers of coherence between different pairs of

Figure 9 Fermionic behavior in a spin 1, observed within a fictitious spin- $\frac{1}{2}$ subspace. A narrowband $\pi/2$ pulse with frequency ω_{rs} first creates coherence between two of the three levels r, s, t . When irradiated at ω_{st} , the coherence then nutates at the rate $\omega_1/2$, displaying the period of 4π characteristic of spin- $\frac{1}{2}$ particles. The sample is a single crystal of perdeuterated hexamethylbenzene. (Reproduced by permission of the American Physical Society from Stoll et al.²⁴)

levels are described, and extensive references to the original literature are compiled in a number of books and review articles.^{1,6-8}

5 DOUBLE QUANTUM EFFECTS IN SPIN- $\frac{1}{2}$ SYSTEMS

Spin- $\frac{1}{2}$ nuclei can be linked into extended coupling networks through mutual interactions, usually isotropic J couplings in liquids and dipole-dipole couplings in solids and liquid crystals. Double quantum coherence and other nonmagnetization modes, together, have played prominent roles in the rapid development of pulse methods applicable to all phases.

Coupling networks in liquids typically are small, restricted by the limited reach of the through-bond J coupling. The finite size of the clusters is advantageous for spin-selective methods, which are designed to tailor either the excitation or detection to match particular coupling patterns. Of particular interest is the application of spin filtering to ^{13}C spectroscopy where, under ^1H decoupling, bonded pairs of ^{13}C nuclei provide two-spin subsystems amenable to double quantum filtering.²⁷ With ^{13}C naturally abundant at only 1%, though, over 98% of the carbon-carbon pairs are formed by the nonmagnetic isotope ^{12}C . Of the others, most contain just one ^{13}C and therefore can support only single quantum coherence. But there is a 1 in 10 000 chance that adjacent carbons are both ^{13}C —the pair well removed from any other nuclei—and signals derived from these groups can be isolated despite the unfavorable statistics. Since double quantum coherence represents the total spin coherence in the ^{13}C – ^{13}C subsystems, there is only one frequency of response: the sum of the chemical shifts from each of the connected carbons. Hence in a filtered two-dimensional spectrum (Figure 10), a double quantum $\rightarrow$ single

Figure 10 Correlations between double quantum and single quantum frequencies in a two-dimensional ^{13}C spectrum of 5 α -androstane. Connections between C-2 and C-3, C-7 and C-8, C-10 and C-1, and C-12 and C-13 are indicated on the spectrum. (Reproduced with permission of the American Chemical Society from Bax et al.²⁷)

quantum pathway is marked by a common frequency along one axis. Any pair of *single quantum* signals sharing this frequency on the other axis is immediately recognized as originating from the same pair of coupled carbons. Analysis of all the spectral connections permits the reconstruction of the carbon skeleton of the molecule, atom by atom, and provides a first step toward a complete understanding of the structure.

Double quantum coherence, homonuclear and heteronuclear, plays at least some part in vast numbers of pulse sequences, too many to describe adequately in a limited space. Just a few of its manifestations might include BIRD, DEPT, and various spectral editing schemes. But perhaps the most common mode of all is not two quantum but *two spin*. The

antiphase magnetization, arising from the coherent superpositions $\alpha\alpha \leftrightarrow \beta\alpha$ and $\alpha\beta \leftrightarrow \beta\beta$ in a spin pair, is ubiquitous in its role as a coherence transfer pathway. It is intrinsic to two-dimensional correlated spectroscopy and to the vast majority of sophisticated pulse sequences applied to liquids.

For two nuclei A and B, the antiphase magnetization is proportional to $\hat{I}_{xA}\hat{I}_{zB}$ in the product operator representation of the density operator. Fully equivalent to the fictitious spin- $\frac{1}{2}$ description, product operators decompose a system of coupled spins $\frac{1}{2}$ into constituent particles each with two levels.²⁸ The coherence is imagined as built up spin by spin, rather than by isolation of pairs of states. An antiphase coherence, specifically, is described as a one-quantum two-spin degree of freedom, namely a collective mode with one active spin and one passive. Qualitatively it is pictured as the transverse, single quantum coherence of spin A ($\hat{I}_{xA}$) responding simultaneously to the two possible orientations of the local field of spin B ($\hat{I}_{zB}$). Unlike normal in-phase coherence $\hat{I}_x$, however, the antiphase mode appears as the *difference* of two operators: $\hat{I}_x^{1-2} - \hat{I}_x^{3-4}$. One component corresponds to B in the α state; the other component, diametrically opposed in the rotating frame, corresponds to B in the β state (Figure 11). An antiphase coherence, although lacking any net magnetization itself, is readily converted to other modes, including both observable one-quantum one-spin terms such as $\hat{I}_{yB}$ as well as double quantum terms such as $\hat{I}_{xA}\hat{I}_{xB}$.

Solids and other oriented systems, in contrast to liquids, often develop extremely large coupling networks via the through-space dipole interactions. Except perhaps in small, relatively isolated molecules, subsystems containing only two spins (and therefore limited to double quantum coherence) are rare. Nevertheless, double quantum *excitation* sequences are used for selective excitation of k -quantum signals and also to 'pump' coherences of very high order, up to 100 or more in dipolar solids. Specially designed pulse trains successively add two quanta to existing superpositions, thereby creating k -quantum modes where $|k| = 2, 4, 6, \dots$. These sequences, moreover, are easily manipulated by phase shifts, and can be configured to yield both a two quantum Hamiltonian $\hat{\mathcal{H}}_{yx}$ and its negative, $-\hat{\mathcal{H}}_{yx}$. Negating the Hamiltonian in any unitary propagator

$$\hat{U}(t) = \exp(-i\hat{\mathcal{H}}t) \quad (17)$$

cannot be distinguished from negating the time, and so the effect is tantamount to reversing the sense of time as the system evolves.²⁰ Time reversal of this sort is crucial for obtaining high-order multiple quantum spectra in solids.

1 INTRODUCTION

Double-quantum (DQ) NMR spectroscopy of dipolar coupled spins in solids under fast magic angle spinning (MAS) is new a tool, by use of which topics of general interest in materials science and bioscience can be addressed. For instance, in advanced synthetic as well as in biological systems self assembly of carefully chosen building blocks is of central importance.^{1–4} Hydrogen bonding and aromatic π - π interactions are key features of supramolecular chemistry.⁵ Despite being highly ordered on a local scale, such systems often do not crystallize. Therefore, their structures cannot be determined by conventional X-ray crystallography or neutron scattering. Alternatives are needed which should provide structural and dynamic information, preferably requiring only small amounts of as-synthesized samples, without the need for isotopic labeling. High resolution solid state ^1H -NMR can meet these requirements,^{6–8} provided that sufficiently selective information can be extracted from the corresponding spectra.

Since 1994 we have systematically pursued the development of solid state ^1H NMR for that purpose by combining fast MAS⁹ and DQ NMR spectroscopy,¹⁰ which makes use of the homonuclear dipole–dipole coupling between protons.^{11,12} The spectral resolution can be increased by use of similar methods exploiting heteronuclear ^1H – ^{13}C dipole–dipole couplings.¹³ These techniques take advantage of the significant simplification of the multispin dipolar coupled network under fast MAS, where two-spin correlations predominate,¹⁴ and have provided new insight in

- hydrogen bonded structures in the solid state¹⁵
- columnar stacking and molecular dynamics of discotics¹⁶
- chain order and translational motion in polymer melts¹⁷
- chain organization on surfaces.¹⁸

This review briefly outlines these new approaches for studying supramolecular organization and demonstrate their advantages with specific examples.

2 HIGH RESOLUTION SOLID STATE NMR

Various aspects of solid state NMR are subjects of other articles in this Encyclopedia. For a full treatment of earlier work including multidimensional techniques, we refer to our extended monograph.¹⁹

2.1 Magic Angle Spinning

A particularly important recent advance in solid state NMR is fast MAS with rotor frequencies $\omega_R > 2\pi \cdot 25 \text{ kHz}$ ⁹ up to $2\pi \cdot 50 \text{ kHz}$ as described by Samoson (see **Magic-angle Spinning Extensions**).²⁰ For most organic solids, the strongest ^1H – ^1H dipole–dipole coupling, e.g., in CH_2 groups with a proton–proton distance of 0.18 nm are of the order of $\omega_D \approx 2\pi \cdot 20.6 \text{ kHz}$. Thus, the condition $\omega_R \geq \omega_D$ can be met even for the strongest dipole–dipole couplings. Since in most cases the remaining spins are further away, the corresponding remote couplings can effectively be ‘spun out’

Figure 1 (a) Simulated MAS NMR spectra for a spin-pair subject to a perturbing spin in an isosceles triangle arrangement for various ratios ξ of the perturbing dipole–dipole coupling ω_D^{pert} to the rotor frequency ω_R . (b) Centreband ($n = 0$) and sideband ($n = 1, 2$) intensities in MAS spectra for the three-spin system in (a) as function of ξ . Solid lines, two- and three-spin correlations; dotted lines, only two-spin correlations.²¹ (Reproduced by permission of Academic Press)

and only the strongest couplings, originating from the shortest distances, are retained. This simple picture is indeed borne out in an elaborate theoretical treatment of multi-spin systems under fast MAS, combining Floquet theory and perturbation theory.¹⁴ The higher-spin contributions are found to scale with increasing powers of the inverse rotor frequency and become less and less important at higher and higher ω_R .

As an example, Figure 1(a) shows MAS NMR spectra for a spin-pair subject to a perturbing spin in an isosceles triangle arrangement for various ratios ξ of the perturbing dipole–dipole coupling ω_D^{pert} to the rotor frequency ω_R .²¹ Sideband patterns are observed, from which the dominant dipole–dipole coupling D^{pair} can be determined straightforwardly as indicated in Figure 1(b). The simulated center and sideband intensities, calculated from simply adding the contributions of pair correlations are very good approximations for the full treatment including three-spin correlations. The linewidths, however, significantly increase with ξ as the dominant term there involves three-spin correlations. Thus, the strongest dipole–dipole couplings can simply be determined from one-dimensional (1D) MAS sideband patterns.

2.2 Homonuclear Double-Quantum Coherences

In order to obtain a structure, the weaker remote dipole–dipole couplings, relating protons of different chemical entities are particularly informative. They can now be determined

by DQ MAS NMR spectroscopy.^{11,12} The basic experimental scheme, a specific pulse sequence and a coherence pathway diagram,²² are shown in Figure 2(a): firstly, a double-quantum coherence (DQC) is excited, which subsequently evolves during an incremented time period t_1 . Afterwards, the DQC is converted into observable single-quantum coherence (SQC), which is detected in the acquisition period. Pure absorption mode 2D spectra are ensured by generating amplitude modulated signals in t_1 through proper selection of symmetric pathways.^{19,22} During excitation and reconversion the *homonuclear* dipole–dipole interaction is recoupled. Numerous ways for achieving this have been developed, as described by Levitt (see **Symmetry-Based Pulse Sequences in Magic-Angle Spinning Solid-State NMR**)²³ (see also Ref.²⁴)

The nature of the corresponding 2D spectra is illustrated in Figure 2(b,c). Here we consider two kinds of pairs of spins, labeled 1 and 2, with different chemical shifts. The excitation of DQ coherence is based on the dipole–dipole coupling between the two spins involved. Thus, if the two kinds of groups are separated (Figure 2(b)), DQ signals can only occur at $2\omega_1$ and $2\omega_2$ along the DQ dimension, i.e., on the diagonal of a 2D plot with proper frequency scaling. These signals reflect the dipolar couplings within the respective groups. Note that distinct from the INADEQUATE experiment in isotropic liquids based on the isotropic scalar

Figure 2 (a) Pulse sequence and coherence transfer pathway of a homonuclear DQ MAS experiment, all pulses have 90° flip angles. (b) Scheme of DQ MAS NMR spectrum for separated spin pairs, (c) for spin pairs in spatial proximity

couplings,²² the intragroup coherences occur despite the fact that the isotropic chemical shifts of the two spins are equal. This reflects the fact that in solids the DQ coherence is generated by the anisotropic dipole–dipole coupling. If the groups are intermixed (Figure 2(c)), DQ coherences between spins of different groups can also be excited. They occur at the sum-frequency $\omega_1 + \omega_2$ in the DQ dimension and can be detected at both frequencies ω_1 and ω_2 in the single quantum dimension. Thus, such a pair of lines in the 2D-NMR spectrum directly maps the spatial proximity between group 1 and group 2. For short excitation times the intensities of the DQ signals are proportional to D_{ij}^2 where D_{ij} describes the dipole–dipole coupling between the two spins involved.

Spectra as discussed in the previous section are obtained in a *rotor-synchronized fashion*, i.e., the t_1 increment is set equal to the rotor period τ_R and yield distance constraints for the dipolar coupled nuclei. More accurate values for dipole–dipole couplings may be obtained from build-up curves of DQC, which for isolated spin pairs, such as doubly labeled ^{13}C – ^{13}C , exhibit an oscillatory behavior.²⁵ Strongly coupled ^1H – ^1H

systems, however, quickly develop multi-spin character and the oscillations are damped out. Nevertheless, even there the initial build-up is dominated by DQCs and can quantitatively be analyzed.^{26,27}

The dipole–dipole coupling constants as well as the geometry of dipolar coupled clusters as, e.g., in triple- or quadruple hydrogen bonds, can much better be elucidated if DQ *spinning sidebands* are generated by choosing a t_1 time increment well below τ_R .^{11,12} Examples calculated for an isolated spin pair are plotted in Figure 3 as a function of $D_{ij}\tau_{\text{exc}}$. Note that these sidebands occur despite the fact that the DQC for an isolated spin-pair does not evolve during the evolution time t_1 . Instead, the *reconversion* is *rotor encoded* because the dipole–dipole Hamiltonian modulated by MAS differs at the beginning of excitation and reconversion. This mechanism is termed *reconversion rotor encoding* (RRE) and occurs whenever the Hamiltonians involved have an amplitude modulation on the rotor phase, which is also the case in MQ MAS experiments on quadrupolar nuclei.^{28,29} The two cases have been compared in detail.³⁰ In actual applications, the rotor frequency ω_R and the excitation time τ_{exc} will be chosen to generate up to third

Figure 3 DQ spinning sideband patterns calculated for increasing values of the product of the dipolar coupling and the excitation time

Figure 4 Pulse sequence for heteronuclear ^1H – ^{13}C correlation experiments based on combining the concepts of REDOR and HMQC. For details see Ref.³⁸ Solid and open bars indicate 90° and 180° pulses, respectively. (Reproduced by permission of American Institute of Physics)

order sidebands in order to achieve sufficient signal-to-noise ratios, yet avoid multi-spin effects, which lead to *evolution rotor modulation* (ERM).³⁰ Notably, multi-spin effects give rise to additional (even-order) sidebands and can, therefore, be easily identified.

2.3 Heteronuclear Multiple-Quantum Coherences

Two-dimensional ^1H DQ MAS experiments as described in Section 2.2 still suffer from the limited spectral resolution in solid state ^1H NMR. Therefore, heteronuclear methods involving ^{13}C or ^{15}N offer significant advantages for obtaining more specific distance constraints. Indeed, if combined with homonuclear ^1H – ^1H decoupling by rotor synchronized multiple pulse sequences³¹ or frequency switched Lee-Goldburg experiments,³² remarkable resolution has been achieved in model compounds³³ as well as biologically relevant systems.³⁴ Once specific ^1H – ^{13}C spin pairs are identified, precise measurement of their dipole–dipole couplings via spinning sidebands also offers a new and efficient way to study molecular dynamics in analogy to ^2H -NMR experiments,¹⁹ yet without the need for elaborate isotope labeling. Rotational-echo double-resonance (REDOR)^{35,36} currently is most popular for determining heteronuclear dipole–dipole couplings in solids. It is based on a particularly simple approach of *recoupling*, i.e., the application of equally spaced π -pulses twice per rotor period on one of the isotopes. When applied under fast MAS in order to efficiently reduce the homonuclear dipole–dipole coupling, REDOR can be combined with multiple-quantum spectroscopy in a whole class of dipolar heteronuclear multiple spin correlation (DIP-HMSC) experiments^{37,38} which are more selective than determining distance constraints via cross polarization and spin diffusion experiments.^{39,40} The basic pulse sequence for a ^1H – ^{13}C heteronuclear multiple-quantum correlation (HMQC) experiment is depicted in Figure 4. As in homonuclear DQ-NMR, the first half of the REDOR recoupling is identified as the excitation period, and the second as the reconversion period. In between, HMQC evolution occurs during t_1 . The ^{13}C chemical shift is fully refocused by π -pulses during excitation, evolution and reconversion.

Similar to the homonuclear case, Section 2.2, precise values for heteronuclear dipole–dipole couplings can be determined via sideband patterns, which are generated through rotor encoding (RRE) as well as evolution (ERM). Consequently, the sideband patterns for an isolated heteronuclear spin pair, plotted as a function of the excitation time in Figure 5(a), exhibit the same features as in the homonuclear case (Figure 3). Again, in actual experiments the excitation times are chosen short enough such that a limited number of sidebands is created and multi-spin effects are minimized for C–H groups. The unavoidable three-spin coherences in rigid CH_2 groups, in fact, lead to efficient dephasing.^{37,38} This can be used for spectral simplification, but also offers an easy way to distinguish mobile methylene groups from rigid ones.

DQ sideband patterns also offer new ways to study the rate and the geometry of rotational motions,^{16,38} where the site selectivity is particularly high for heteronuclear DQ coherences. In Figure 5(b) simulated sideband patterns are plotted for the C–H group which is a sensitive probe of phenylene rotation, often met in practice.¹⁹ At low temperatures one

Figure 5 (a) Calculated HMQC spinning sideband patterns for a single IS spin pair for increasing values of the ratio of the product of the dipolar coupling strength D_{IS} multiplied by the number of pump cycles N_{rcpl} and the rotor frequency ω_{R} . For details see.³⁸ (b) Calculated heteronuclear DQ MAS NMR spinning sideband patterns for rotating phenylene groups and different flip angles α as indicated ($N_{\text{rcpl}}D_{\text{IS}}/\omega_{\text{R}} = 1.67$). (Reproduced by permission of American Institute of Physics)

would expect small-angle librations. With increasing temperatures the angular excursions will increase until full rotation might be reached. The resulting motionally averaged dipolar couplings are readily calculated via the internet by use of our NMR-WEBLAB.⁴¹ As shown in Figure 5(b), the sideband patterns show a marked dependence of the flip angle α . A recent experimental example is provided by the restricted phenylene motion in polyphenylene dendrimers,⁴² a new type of nanomaterials.¹

3 APPLICATIONS

3.1 Spin Counting

The classic application of MQ NMR in solids as pioneered by A. Pines in the early 1980s is spin counting.⁴³ He showed that it is possible to excite homonuclear MQCs comprising more than 100 spins, by exploiting the through-space dipole–dipole coupling. With this technique it was possible, for instance, to prove the existence of small clusters of proton spins on the surface of silica catalyst supports.⁴⁴ In fact, the growth of MQCs in a spin cluster as depicted in Figure 6(a) can be described by a statistical model. The intensities of the

coherence orders follow a Gaussian distribution, the width of which increases with excitation time. Such behavior indicates that the build-up of homonuclear MQCs amongst strongly coupled spins occurs via a random walk. The different pathways indicated in Figure 6(a) result from the non-localized and, therefore, non-selective growth of the spin-cluster. As demonstrated in Figure 6(c), this behavior is also found under MAS conditions, provided efficient recoupling is achieved.²⁷

Distinct from that, MQCs in the I-spin subspace of a heteronuclear IS NMR experiment are excited via the dipole–dipole coupling of all these spins to a single S spin. For this selected site the multitude of surrounding I spins creates

Figure 6 Growth of spin clusters as probed in homonuclear (a) and heteronuclear (b) MQ NMR experiments. Experimental examples for adamantane ($^1\text{H} \cdots ^1\text{H}$ homonuclear, (c)), for details see Ref.²⁷ and L-alanine ($^1\text{H} \cdots ^{13}\text{C}$ heteronuclear, (d)), for details see Ref.³⁸ (Reproduced by permission of American Institute of Physics, (a), (b), (d) and Academic Press, (c))

a local field. The number of proton (I) spins incorporated in the HMQ can only grow by including remote spins with sufficient couplings to the S spin [Figure 6(b)]. Thus, build-up of higher spin coherences will converge with time. As shown in Figure 6(d), higher order MQCs are indeed observed for the carboxyl carbon in uniformly ^{13}C labeled L-alanine,³⁸ but the intensity distribution obviously is not Gaussian. Thus, heteronuclear spin counting indeed probes a selected local environment and therefore is anticipated as a new tool for structural investigations.

3.2 Structure

3.2.1 Hydrogen Bonding

Protons in hydrogen bonded structures exhibit ^1H chemical shifts well away from the aliphatic peaks. Therefore, high

resolution ^1H solid state NMR is ideally suited for investigating such systems as noted early on.⁴⁵ Moreover, correlations between the ^1H isotropic chemical shifts and the hydrogen-bond strength specified by $\text{O}\cdots\text{H}$ or $\text{O}\cdots\text{O}$ distances from single-crystal analyses have been established.⁴⁶ The first example of the new kind of information about proton–proton distance constraints available from solid state DQ MAS NMR was the investigation of the unusual hydrogen bonded structures in benzoxazine dimers.¹⁵ These dimers are of interest as model compounds for a new class of phenolic materials, the polybenzoxazines prepared by Ishida and coworkers.⁴⁷ These systems combine several favorable properties, such as near-zero shrinkage on polymerization as well as low water absorption, which are attributed to their favorable hydrogen-bonding.

Figure 7(a) shows the superimposed ^1H MAS NMR spectra of both the methyl (solid line) and ethyl (dashed line)

Figure 7 (a) ^1H MAS NMR spectra of benzoxazine dimers at 500 MHz. Solid line, methyl derivative; dotted line, ethyl derivative. (b), (c) Low field region of the ^1H DQ MAS NMR spectrum of the methyl and ethyl derivative, respectively. (d), (e) Schematic arrangement of the methyl dimers into pairs (d) and the ethyl dimers into extended chains (e). For details see Ref.¹⁵ (Reproduced by permission of American Chemical Society)

derivative. The spectra differ markedly in the low-field region, which gives a first hint towards different hydrogen bond arrangements in the two cases. The differences are even more marked in the ^1H DQ MAS NMR spectra, whose low-field regions are displayed in Figures 7(b) and 7(c). The labels (A, B, C, and D) refer to the SQ resonances of the hydrogen bonded, aromatic, and aliphatic protons, respectively. The peaks in the DQ spectrum indicate proximities of protons within about 0.35 nm^{15} and are labeled accordingly as AB, AC, etc. The most striking differences between the methyl- and ethyl-dimer spectra are the strong aromatic auto peak (CC) and only weak intensity (AC) indicating a DQC between a $\text{O}\cdots\text{H}\cdots\text{N}$ and an aromatic proton for the methyl-dimer, while the situation is reversed for the ethyl-derivative. As discussed in detail elsewhere,¹⁵ this indicates pair formation from two dimers, Figure 7(d) in the methyl-derivative, and extended hydrogen bonded chains, Figure 7(e) for the ethyl-dimers.

These structural differences have meanwhile been confirmed by X-ray diffraction.

Another example of elucidating complex hydrogen bonded structures is provided by our study of supramolecular polymers⁴⁸ coupled via quadrupole bonds in 2-ureido-4-pyrimidone units, where keto- and enol tautomers in the solid state could clearly be distinguished by DQ MAS NMR.⁴⁹ DQ spinning sideband patterns have also been used to locate the protons in bilirubin, a compound of considerable medical importance. It is a product of the metabolism of hemoglobin from red blood cells. Due to an unusually strong intramolecular hydrogen bonding arrangement, bilirubin itself is insoluble in water and can only be removed from the body after being conjugated enzymatically with glucuronic acid.⁵⁰ Inefficient removal of bilirubin from the body manifests itself as jaundice. Solid state NMR now has provided proton-proton distances with an accuracy of $\pm 0.002\text{ nm}$ in this important system.⁵¹

Figure 8 Calculated ^1H MAS NMR spectra and schematic ^1H DQ MAS NMR spectra for different arrangements of HBC discs, staggered in different directions (a, b). Experimental ^1H spectra of HBC- C_{12} together with staggered arrangement (c). For details see Ref.⁵⁴ (Reproduced by permission of American Chemical Society)

3.2.2 Aromatic π - π Interactions in Columnar Structures and Guest-Host Complexes

In addition to hydrogen-bonding, the ^1H chemical shifts are very sensitive to ring currents associated with π -electrons in aromatic moieties.⁵² While in solution, the isotropic molecular tumbling removes most of the π -shifts, in the solid state the protons are exposed to the π -electrons of nearby aromatic moieties, be they intra- or intermolecular. The latter information is particularly valuable for elucidating supramolecular structures.^{2,5} A clear-cut example is provided by the columnar stacking of substituted hexa-*peri*-hexabenzocoronene (henceforth referred to as HBC). Opposed to solution or the liquid crystalline phase, where the discs tumble isotropically or rotate rapidly around the column axis, in the solid three distinct aromatic lines are observed in the aromatic region of the ^1H -NMR spectrum¹⁶ (Figure 8). The DQ-spectrum exhibits a strong CC auto and two AB cross peaks, which implies the presence of only two types of pairs of aromatic protons, $\text{H}_\text{A}-\text{H}_\text{B}$, $\text{H}_\text{C}-\text{H}_\text{C}$. For quantitative analysis, advanced quantum chemical calculations of NMR chemical shifts are needed.⁵³ They show that staggered arrangements of the HBC moieties indeed give rise to π -shifts of several ppm.⁵⁴ The assignment, which of the chemically shifted protons form pairs is achieved by DQ-NMR and is essential to determine the type of staggering. In a herringbone-structure which corresponds to that of unsubstituted HBC (Figure 8(a)) none of the carbons are aligned, whereas in structure (b) half of the carbons are located directly above or below a carbon of the adjacent layer resembling the packing in graphite. The latter (Figure 8(b)) could clearly be excluded, because it does not match the experimental 2D NMR pattern (Figure 8(c)). The pattern in Figure 8(a), however, agrees well with the experimental one. This proves the specific packing arrangement hypothesized earlier,¹⁶ that this alkylsubstituted system adopts the structure of unsubstituted HBC itself. Through-space π -shifts are remarkably long-range, with an aromatic ring at a distance of 0.7 nm still exerting a measurable influence. Thus, in the final simulation, three HBC moieties had to be taken into account (Figure 8(c)).

The combination of ^1H DQ MAS-NMR with advanced ab initio quantum chemical calculations also proved essential for elucidating the structure of a supramolecular guest-host complex. The receptor shown in Figure 9(a) belongs to the family of molecules termed molecular tweezers due to their concave-convex topology and ability to selectively form complexes with electron-deficient compounds.⁵⁵ An X-ray crystal structure is available for this system, offering an opportunity to check the reliability of the spectroscopic approach.⁵⁶ Figure 9(b) presents a rotor-synchronized ^1H DQ MAS spectrum of the complex (Figure 9(a)). Despite the high field (700 MHz) used, the spectral resolution for the many aromatic protons is unsatisfactory. The different sites can much better be distinguished in a heteronuclear correlation spectrum (Figure 9(c)) which was recorded with the REPT-HSQC experiment.³⁷ The two overlapping ^{13}C lines at 128.7 and 129.6 ppm are assigned to the guest CH groups (5a and 5b), which are well separated by 3.6 ppm in the ^1H -dimension. This demonstrates that the π -shifts are much more significant for the protons than they are for the carbons.^{54,56} In the present case, the binding of the electron-deficient 1,4-dicyanobenzene guest in the complex is such that the symmetry of the molecular tweezer is broken (Figure 9(a)) and the two adjacent

guest protons experience the π -shifts due to the host to largely different degrees. Moreover, the end pair of aromatic protons are directed into the ring current of the naphthalene unit of the next host, which explains the π -shifted 4 ar^{II} resonance.⁵⁶ Thus both, the guest-host complexation, as well as the packing of the “loaded” tweezers within the supramolecular solid can be probed by solid state NMR and quantified by ab initio calculation.

3.2.3 Surface Studies

The high sensitivity of ^1H NMR makes it possible to study defect sites and molecules adsorbed at surfaces in a straightforward way.⁴⁴ Two examples are discussed. The first concerns a ^1H -MQ MAS NMR study of defect sites in a zeolite.⁵⁷ As in supramolecular systems, the structures of defects are difficult to study in these industrially important microporous solids,⁵⁸ because the defects are usually not ordered in the crystallographic sense and, therefore, are not easily amenable to analysis by diffraction methods. Figure 10(a) shows the 2D ^1H DQ MAS NMR spectrum of an as-made all silica ZSM-12 zeolite.⁵⁷ The signal at 10 ppm in the SQ dimension is due to a DQC generated by the cluster of silanol protons of the defect site. The observation of a strong centreband in the ^1H DQ MAS spinning sideband pattern (Figure 10(b)) proves that at least three silanol groups are engaged in hydrogen bonding within the defect site. These results have important implications concerning the nucleation mechanism of high-quality zeolites, as they provide new information on the structure of charge-compensating units in the zeolite colloidal precursors.

In another example ^1H DQ MAS NMR recently has also provided new insight in the packing of polyelectrolyte multilayers (PEMs) on silica colloids.¹⁸ These systems, generated by alternate adsorption of anionic and cationic polymers are being explored for numerous applications ranging from photonics to enzyme encapsulation.^{59,60} Fast MAS NMR at high fields (700 MHz) of such systems is able to distinguish, e.g., water adsorbed at the surface from that in the PEM and the silanol groups. Two-dimensional ^1H DQ MAS NMR, however, is needed to probe the organization of the polyelectrolytes within the multilayers. The DQ spectra (Figure 10) exhibit cross-peaks between the aromatic protons of the poly(styrene sulfonate) (PSS) polyanion and the poly(diallyldimethyl-ammonium) (PDADMAC) polycation in both, the bulk complex and the multilayers. These findings¹⁸ are consistent with conclusions based on less direct experimental probes that these polyelectrolyte multilayers are structurally very similar to the corresponding bulk complexes.⁶¹

3.3 Dynamics

3.3.1 Axial Motion of Discs in Columnar Liquid Crystals

A unique strength of solid state NMR is its ability to probe molecular dynamics over many orders of magnitude with site selectivity and specific geometric sensitivity.^{19,62} High resolution DQ MAS of dipolar coupled spins has further broadened our tools in this area. This is illustrated by a few examples. Consider as a particularly simple case the rotation of the discs around the column axis in discotic liquid crystals.⁶³

Figure 9 (a) Solid state packing of a molecular tweezer. (b) ^1H DQ MAS NMR spectrum at 700 MHz, and (c) ^1H - ^{13}C HSQS MAS NMR correlation spectrum, for details see Ref.⁵⁶

In the past, studying this motional process required ^2H NMR of selectively labeled systems, which was indeed done for HBC.⁶⁴ The effort seemed justified in view of the favorable properties of these systems, i.e., extremely stable mesophase and record charge carrier mobility along the column axis.⁶⁵ This tedious approach can now be circumvented. Figure 12 presents ^1H DQ MAS spinning sidebands of HBC- C_{12} , containing C_{12} alkyl chains, in (a) the crystalline and (b) the LC phases.¹⁶ The aromatic protons are grouped as well separated pairs and, thus, an analysis within the spin-pair approximation is appropriate. As is evident from the insets on the right of Figure 12 the DQ-spinning sideband patterns are very sensitive to the strength of the dipolar coupling, which can be determined with high accuracy to yield values of (15 ± 0.9) kHz and (6 ± 0.5) kHz in the solid and the LC phase, respectively. The

reduction factor due the axial motion of the discs is thus 0.4 corresponding to an order parameter of 0.8, remembering that for a completely regular column the H-H vectors would be at right angles to the column axis and the reduction factor would be 0.5.¹⁹ The reduced order parameter indicates additional out-of-plane motion in addition to the axial rotation.

The limited order of these systems also shows up in the X-ray diffraction pattern displayed in Figure 13(a). The order can be increased by inserting phenylene units between the core and the alkyl chains (HBC-Ph C_{12}),⁶⁶ as is evident from the sharper X-ray reflections in Figure 13(b). In ^1H NMR, however, we cannot resolve the core and the exophenyl moieties. This can be achieved by heteronuclear ^1H - ^{13}C DQ NMR applying REPT-HMQC techniques.³⁷ Indeed, analysis of the sideband patterns for the C-H groups (Figure 13, lower part) yields core

Figure 10 (a) ^1H DQ MAS NMR spectrum (500 MHz) of an all silica ZSM zeolite. (b) Sideband pattern for the hydrogen bonded protons, for details see Ref.⁵⁷ (Reproduced by permission of American Chemical Society)

order parameters of 0.78 ± 0.09 and 0.93 ± 0.09 for HBC- C_{12} and HBC- PhC_{12} , respectively, indicating less out-of-plane mesogen mobility in the latter. The ease with which this information is obtained with 10 mg of as-synthesized samples made it possible to report such findings together with the synthesis of these new materials.⁶⁶

3.3.2 Slow Motions from Double-Quantum Exchange NMR

Multidimensional exchange NMR spectroscopy provides unique information about the time scale as well as the geometry of slow molecular motions,¹⁹ latest developments are described by Schmidt-Rohr (see **Centerband-Only Detection of Exchange (CODEX): Efficient NMR Analysis of Slow Motions in Solids**).⁶⁷ Extending DQ NMR spectroscopy into that area, therefore, represented a special challenge. Recently, such a homonuclear DQ-DQ exchange experiment has been designed⁶⁸ by combining two DQ experiments as depicted in Figure 14(a). The dipole-dipole coupling between two distinct spins is used to generate a DQ coherence, and the orientation dependent coupling is measured by means of the DQ-MAS sideband pattern before and after a mixing time. In a

reduced three-dimensional experiment, the two DQ-sideband patterns are correlated, resulting in a DQ-DQ sideband pattern which is sensitive to the reorientation angle. By referencing the DQ-DQ time signal, the information content of the pattern is divided into the sidebands and the centreband, with the former reflecting only the moieties which have undergone a reorientation changing the dipole-dipole coupling, and the latter predominantly containing contributions from moieties which retained their dipole-dipole coupling because they remained in, or returned to, their initial position. Hence a single sideband pattern provides access to the reorientation angle and the relative number of sites characteristic of the motional process. As a first example, Figure 14(b) displays calculated (black) and experimental (gray) ^{13}C - ^{13}C DQ MAS sideband patterns for the crystalline phase of doubly labeled poly(ethylene). The exchange spectra reflect the 180° flip motion due to the slow α -process of this material, yielding a C-C reorientation angle of $70 \pm 5^\circ$ in accord with 2D dipolar exchange NMR experiments on the same sample under static conditions.⁶⁹ One of the advantages of the MAS technique is its ability to probe the chain motion also in the non-crystalline regions, which is particularly important in view of the reviewed interest in the crystallization process of semicrystalline polymers⁷⁰ and the relation of the α -process to ultradrawability of such polymers.⁷¹

3.3.3 Chain Order and Translational Motion in Polymer Melts

High resolution DQ MAS NMR also offers new possibilities to probe dynamic processes involving considerably longer length scales. Figure 15 displays the ^1H DQ MAS NMR spectrum of 1.4 poly(butadiene) (PB) in the melt. The rapid segmental motion largely averages intra- and intermolecular dipole-dipole couplings, such that narrow lines result. Despite of that, strong auto- and cross-DQ peaks are observed, from which residual dipole-dipole couplings between the different protons can be determined.¹⁷ They result from the fact that the chain motion in an entangled melt is not completely isotropic on intermediate length- and timescales. Numerous ways have been designed to probe the resulting dynamic order parameters by NMR.⁷² ^1H DQ MAS NMR is the only way which can clearly distinguish *intra*- and *intergroup* couplings, and therefore determine order parameters for vectors directed *along* the chain, which were found to be considerably higher than anticipated.¹⁷

In order to quantify our findings, the measured order parameters are analyzed in terms of the celebrated reptation model of chain motion, formulated by De Gennes⁷³ and Doi and Edwards.⁷⁴ As depicted in Figure 16(a) the reptation model considers single chains subject to spatial restrictions due to entanglements, which are considered to act effectively like a tube through which the selected chain reptates. Four separate length- and timescales are distinguished (Figure 16(a)). In the different regimes different scaling laws for the mean-square displacement of chain segment due to *translational* motion are predicted, which also show up in the correlation function $C_R(t)$ probed by the residual dipole-dipole couplings, Figure 16(b). Here, the crossover from regime II ($t^{-1/4}$) to regime III ($t^{-1/2}$) is most indicative of reptation.^{17,75,76} This crossover is indeed observed in polymer melts as shown for

Figure 11 ^1H DQ MAS NMR spectra (700 MHz) for a PSS/PDADMAC polyelectrolyte complex (a) and polyelectrolyte multilayer on a silica surface (b). For details see Ref.¹⁸

Figure 12 ^1H - ^1H DQ spinning sideband patterns of HBC- C_{12} in the solid state (a) and in the columnar liquid crystalline phase (b), where the discs rotate around the column axis as indicated. For details see Ref.¹⁶ (Reproduced by permission of American Chemical Society)

PB in Figure 16(c),^{17,76} which forces us to conclude that the characteristic length scale for the residual dipole-dipole couplings is indeed the entanglement length, i.e., nanometers.^{73,74} Thus, DQ NMR emerges as a simple alternative to neutron

scattering for probing the chain organization of polymers.⁷⁷ Further insight was provided through a recent study,⁷⁶ where the effect of restricting the chain motion by anchoring one or both chain ends in polystyrene (PS)-PB blockcopolymers

Figure 13 Comparison of powder wide angle X-ray patterns (a) and heteronuclear ^1H - ^{13}C DQ spinning sideband patterns (b) of HBC-C₁₂ (a) and HBC-PhC₁₂ (b). For details see Ref.⁶⁶

was investigated (Figure 16(c)). Not only did the chain motion slow down, the order parameters were found to increase drastically in these systems, where the polymer melt is confined to lamellae of a few tens of nm. These observations lead us to conclude that amorphous polymers are, in fact, structured in terms of nanodomains,⁷⁶ which is also consistent with new views of polymer crystallization from the melt.⁷⁰

4 CONCLUSIONS AND OUTLOOK

Only a few years after the first DQ MAS spectra of strongly dipolar coupled solids have been recorded¹¹ this type of spectroscopy has emerged as a powerful tool for structural and dynamical elucidation of complex systems. This overview has focused on applications in soft matter research, i.e., on supramolecular organic systems, where spectra are recorded on small amounts (10–15 mg) of as-synthesized samples and the results are obtained overnight; but the methodology can be applied in general. For instance, high resolution DQ MAS NMR spectroscopy of isotopically labeled systems of biological interest yields torsional angles in peptides^{78,79}

and thus important information about the chain conformation. The sensitivity of ^1H chemical shifts to ring current in aromatic systems has been exploited in determining the packing of porphyrines.³⁴ The full information about distances and the relative orientation of specific moieties is available from DQ-NMR spectroscopy on static samples of specifically labeled materials⁸⁰ and has provided important information about the chain conformation and packing of synthetic macromolecules.⁸¹ Last, but not least, DQ MAS NMR spectroscopy has provided hitherto inaccessible information about the connectivity of building blocks and medium range order of inorganic glasses.^{82,83}

The development of the technique is far from complete. Major advances are expected in the years to come. For instance, selection of coherence pathways by pulsed field gradients, well-established in high-resolution NMR in liquids, has recently been demonstrated in rotating solids.^{84,85} Likewise, inverse detection and heteronuclear editing has been realized in MAS NMR in both, synthetic polymers and biopolymers.^{86,87} Indeed, an increase of the signal to noise ratio by a factor of 10 has been achieved for ^{15}N by such an approach.⁴⁹ Thus solid state NMR is envisaged to become as valuable a tool for the supramolecular chemist as solution state NMR is for the synthetic chemist today.

1 INTRODUCTION

The proper treatment of a spin subject to two or more noncommuting interactions is a familiar problem in nuclear magnetic resonance. In practice, various interactions usually differ markedly in magnitude, which enables one to choose the eigenfunctions of the dominant term as a zeroth-order approximation. (Throughout this discussion, the Zeeman interaction is considered dominant. Hence, the high-field approximation obtains). The effect of lesser interactions can be treated in the context of standard perturbation theory. A classic example is the case of a spin under the influence of a laboratory-fixed Zeeman interaction and a static, molecule-fixed quadrupole interaction. However, in certain situations, the first-order correction vanishes identically and it may be necessary to consider effects derived from higher-order perturbation theory. A well-known example is the treatment of the $\frac{1}{2} \leftrightarrow -\frac{1}{2}$ central transition of a half-integer spin subject to both Zeeman and quadrupolar interactions.

In contrast, when motions effectively average molecule-fixed interactions, first-order effects associated with quadrupole, dipole–dipole, or anisotropic electronic shieldings disappear completely in spherically symmetric or isotropic media. Nevertheless, if the averaging motions are slow on the timescale associated with reciprocal Larmor frequencies, a second-order shift of the Zeeman energy occurs even though first-order corrections are quenched.

Relaxation phenomena in the motionally narrowed regime are described using second-order perturbation theory and it is anticipated that second-order dynamic frequency shifts of Zeeman energies are embodied in relaxation theory. In principle, the dynamic frequency shift yields both structural and dynamic information similar to conventional relaxation parameters such as $(1/T_1)$, $(1/T_2)$ or $(1/T_{1\rho})$, over a nominal range of molecular motions.

In Redfield's seminal exposé on the subject of second-order perturbation theory applied to relaxation phenomena, the dynamic frequency shift was explicitly ignored. However, in the more widely accessible version¹ of this theory, the dynamic frequency shift was acknowledged. Abragam, in his classic monograph,² also considered this term. More detailed discussions of the dynamic frequency shift, both in context

of the ESR^{3,4} or NMR^{5,6} experiment, exist in the published literature.

2 SEMICLASSICAL THEORY OF SPIN RELAXATION

In the absence of applied rf fields, the interaction between a nuclear spin and the extranuclear environment can be written as $\hat{\mathcal{H}}(t) = \hat{\mathcal{E}} + \hat{\mathcal{F}}(t)$, where $\hat{\mathcal{E}} = \langle \hat{\mathcal{H}}(t) \rangle$ and $\hat{\mathcal{F}}(t) = \hat{\mathcal{H}}(t) - \hat{\mathcal{E}}$. The influence of $\hat{\mathcal{E}}$ is revealed through chemical shift and multiplet structure. The term responsible for nuclear spin relaxation, $\hat{\mathcal{F}}(t)$, can be cast in the form:

$$\hat{\mathcal{F}}(t) = \sum_{\eta} \hat{\mathcal{F}}^{\eta} = \sum_{\eta} \xi_{\eta} \sum_k (-1)^k \hat{T}_{\eta}^k V_{\eta}^{-k}(t) \quad (1)$$

In general, the total interaction Hamiltonian, $\hat{\mathcal{F}}(t)$, is composed of a number of distinct couplings or relaxation pathways (η). Each interaction has been partitioned into a symmetrized product of classical lattice functions (V), characteristic interaction coupling constants (ξ), and spin operators ($\hat{T}$) which occur in Hermitian adjoint pairs, $(\hat{T}_{\eta}^k)^{\dagger} = (-1)^n \hat{T}_{\eta}^{-k}$. The simple decomposition implicit in equation (1) obtains for interactions with axial symmetry.

In the limit where it is possible to define a time τ such that $\langle \hat{\mathcal{F}}(\tau) \hat{\mathcal{F}}(0) \rangle \ll |\hat{\mathcal{F}}|^2$ and $\tau |\hat{\mathcal{F}}| \ll 1$, the time evolution of individual matrix elements of a thermally normalized, reduced spin density operator, $\chi(t)$, are described by a simple set of linearly coupled first-order equations,¹

$$\begin{aligned} (d/dt) \chi_{\alpha\alpha'}(t) = & -i\omega_{\alpha\alpha'} \chi_{\alpha\alpha'}(t) \\ & + \sum_{\alpha''} \sum_{\alpha'''} \mathcal{R}_{\alpha\alpha'\alpha''\alpha'''} \chi_{\alpha''\alpha'''}(t) \end{aligned} \quad (2)$$

where

$$\begin{aligned} \mathcal{R}_{\alpha\alpha'\alpha''\alpha'''} = & \sum_k \sum_{\eta} \sum_{\eta'} [G_k^{\eta\eta'}(\omega_{\alpha\alpha''}) + G_k^{\eta\eta'}(\omega_{\alpha''\alpha'})] \\ & \times (T_{\eta}^k)_{\alpha\alpha''} (T_{\eta'}^{-k})_{\alpha''\alpha'} \\ & - \delta_{\alpha\alpha''} \sum_{\beta} G_k^{\eta\eta'}(\omega_{\alpha''\beta}) (T_{\eta}^k)_{\alpha''\beta} (T_{\eta'}^{-k})_{\beta\alpha'} \\ & - \delta_{\alpha'\alpha'''} \sum_{\beta} G_k^{\eta\eta'}(\omega_{\beta\alpha''}) (T_{\eta}^k)_{\alpha\beta} (T_{\eta'}^{-k})_{\beta\alpha''} \end{aligned} \quad (3)$$

The complex spectral density is defined as

$$\begin{aligned} G_k^{\eta\eta'}(\omega) = & \xi_{\eta} \xi_{\eta'} \int_0^{\infty} \langle V_{\eta}^{-k}(t - \tau) V_{\eta'}^k(t) \rangle \exp(-i\omega\tau) d\tau \\ = & J_k^{\eta\eta'}(\omega) - iL_k^{\eta\eta'}(\omega) \end{aligned} \quad (4)$$

The abbreviated matrix elements introduced in equations (3) and (4) are defined by the expressions, $\chi_{\alpha\beta} = \langle \alpha | \hat{\chi} | \beta \rangle$, $(T_{\eta}^k)_{\alpha\beta} = \langle \alpha | \hat{T}_{\eta}^k | \beta \rangle$, and $\omega_{\alpha\beta} = -\omega_{\beta\alpha} = \langle \alpha | \hat{\mathcal{E}} | \alpha \rangle - \langle \beta | \hat{\mathcal{E}} | \beta \rangle$. Equation (3) includes both autocorrelation ($\eta = \eta'$) and cross-correlation ($\eta \neq \eta'$) spectral densities.

Detailed derivations, implicit limitations and subsequent simplifications of equations (2)–(4) can be found in articles by Redfield¹ or Hubbard.⁷

The imaginary contribution, $L_k^{\eta\eta'}(\omega)$, is defined as the Hilbert transform of $J_k^{\eta\eta'}(\omega)$ and identifies with a frequency shift. Equation (4) is an affirmation of the Kramers–Kronig relationship which relates the real and imaginary components of the Fourier transform of a causal function.

3 THE DYNAMIC FREQUENCY SHIFT

In the absence of overlapping transitions, equation (2) can be written in a simpler form. For populations $\alpha = \alpha'$ and $\alpha'' = \alpha'''$,

$$-(d/dt)\chi_{\alpha\alpha}(t) = \sum_{\alpha'' \neq \alpha} W_{\alpha\alpha''}[\chi_{\alpha\alpha}(t) - \chi_{\alpha''\alpha''}(t)] \quad (5)$$

where

$$W_{\alpha\alpha''} = 2 \sum_k \sum_{\eta} \sum_{\eta'} (T_{\eta}^k)_{\alpha\alpha''} (T_{\eta'}^{-k})_{\alpha''\alpha} J_{k'}^{\eta\eta'}(\omega_{\alpha\alpha''}).$$

Because

$$L_k^{\eta\eta'}(\omega) + L_k^{\eta\eta'}(-\omega) = 0 \quad (6)$$

populations are unaffected by the imaginary contribution.

Similarly, the free evolution of the coherence between states $|\alpha\rangle$ and $|\alpha'\rangle$ is described as:

$$-(d/dt)\chi_{\alpha\alpha'}(t) = [i(\omega_{\alpha\alpha'} + \Omega_{\alpha\alpha'}) + (1/T_2)_{\alpha\alpha'}]\chi_{\alpha\alpha'}(t) \quad (7)$$

where

$$\begin{aligned} (1/T_2)_{\alpha\alpha'} = & - \sum_{\eta} \sum_{\eta'} J_0^{\eta\eta'}(0) \left\{ 2(T_{\eta}^0)_{\alpha\alpha} (T_{\eta'}^0)_{\alpha'\alpha'} \right. \\ & + \sum_{\eta} \{ [(T_{\eta}^0)_{\alpha\alpha}]^2 + [(T_{\eta}^0)_{\alpha'\alpha'}]^2 \} \\ & \left. + (1/2) \left\{ \sum_{\beta \neq \alpha} W_{\alpha\beta} + \sum_{\beta \neq \alpha'} W_{\alpha'\beta} \right\} \right\} \quad (8) \end{aligned}$$

The dynamic frequency shift is defined as

$$\begin{aligned} \Omega_{\alpha\alpha'} = & \sum_{\beta \neq \alpha} \sum_k \sum_{\eta} \sum_{\eta'} [(T_{\eta}^k)_{\alpha'\beta} (T_{\eta'}^{-k})_{\beta\alpha'} L_k^{\eta\eta'}(\omega_{\beta\alpha'}) \\ & + (T_{\eta}^k)_{\beta\alpha} (T_{\eta'}^{-k})_{\alpha\beta} L_k^{\eta\eta'}(\omega_{\alpha\beta})] \quad (9) \end{aligned}$$

For dipole–dipole (D_{IS}), axially symmetric anisotropic shielding (SA_I), and axially symmetric quadrupolar (Q_I) interactions modulated by symmetric-top, diffusional reorientation

characterized by the two diffusion constants, $D_{\parallel} = D_{zz}$ and $D_{\perp} = D_{xx} = D_{yy}$, $L_k^{\eta\eta'}(\omega)$ is defined as

$$\begin{aligned} L^{\eta\eta'}(\omega) = & (16\omega\pi)^{-1} \xi_{\eta} \xi_{\eta'} \left[\frac{(3 \cos^2 \theta_{\eta} - 1)(3 \cos^2 \theta_{\eta'} - 1)}{1 + (\omega\tau_{20})^{-2}} \right. \\ & + \frac{12 \cos \theta_{\eta} \cos \theta_{\eta'} \sin \theta_{\eta} \sin \theta_{\eta'} \cos(\phi_{\eta} - \phi_{\eta'})}{1 + (\omega\tau_{21})^{-2}} \\ & \left. + \frac{3 \sin^2 \theta_{\eta} \sin^2 \theta_{\eta'} \cos(2\phi_{\eta} - 2\phi_{\eta'})}{1 + (\omega\tau_{22})^{-2}} \right] \quad (10) \end{aligned}$$

Equation (10) applies to isotropic media where the suppressed k index is superfluous. The angle θ defines the angle between the principal axes of the diffusion and interaction tensors. The three correlation times are defined as $1/\tau_{2n} = 6D_{\perp} + n^2(D_{\parallel} - D_{\perp})$. For isotropic motions, $\tau_{2n} \sum \tau_2$, equation (10) simplifies accordingly, $L^{\eta\eta'}(\omega) = (8\omega\pi)^{-1} (\xi_{\eta} \xi_{\eta'}) (3 \cos^2 \Theta_{\eta\eta'} - 1) (1 + (\omega\tau_2)^{-2})^{-1}$. The angle $\Theta_{\eta\eta'}$ is defined as the angle between the principal axes of interactions η and η' . If $\omega\tau_{20}$, $\omega\tau_{21}$, $\omega\tau_{22} \gg 1$, $L^{\eta\eta'}(\omega) = (8\omega\pi)^{-1} (\xi_{\eta} \xi_{\eta'}) (3 \cos^2 \Theta_{\eta\eta'} - 1)$. In this slow motion limit, the maximum shift associated with an autocorrelated term is simply $(4\omega\pi)^{-1} (\xi_{\eta})^2$. Appropriate interaction constants for a spin I subject to (I, S) dipole–dipole, anisotropic shielding or quadrupolar interactions are $\xi_{D_{IS}} = (6\pi/5)^{1/2} \gamma_I \gamma_S \hbar (r_{IS})^{-3}$, $\xi_{SA_I} = (2\pi/15)^{1/2} \Delta\sigma_I \omega_I$ (with $\omega_I = \gamma_I B_0$) and $\xi_{Q_I} = (3\pi/40)^{1/2} e^2 q_I Q_I / h$.

Only in the limit where motions are relatively isotropic—and $\omega\tau_2$ is close to one—will the dynamic shift be comparable to the adiabatic linewidth parameter.⁸ In general, this argument is used to justify the neglect of second order dynamic frequency shifts in magnetic resonance. However, for relaxation studies in the vicinity of the T_1 minimum, or for the investigation of systems where linewidths have no adiabatic contribution, the dynamic frequency shift may play an important role.

In Figure 1, the adiabatic term, $G^{\eta\eta}(0) \sum G^{\eta}(0) = J^{\eta}(0)$, and the real and imaginary components of the spectral density, $G^{\eta}(\omega_I)$, are plotted as functions of an isotropic reorientational correlation time (τ_2) measured in units of the reciprocal Larmor frequency, ω_I^{-1} . Because the interaction is unspecified, the ordinate is not scaled. The ratio of plateau values for $J^{\eta}(0)$ and $L^{\eta}(\omega_I)$ is on the order of $\omega_I \xi_{\eta}$.

4 DYNAMIC FREQUENCY SHIFTS FOR SOME SIMPLE SPIN SYSTEMS

4.1 The Two Unlike Spin- $\frac{1}{2}$ System

Consider the scalar coupled, $I = \frac{1}{2}$, $S = \frac{1}{2}$ spin system with both spins being relaxed by anisotropic shieldings and a mutual dipole–dipole interaction. In the absence of second-order shifts, the four single quantum transitions occur at frequencies $\omega_S \pm J/2$ and $\omega_I \pm J/2$, where J is the scalar

Figure 1 Schematic plots of various relaxation parameters versus the isotropic, reorientational correlation time, τ_2 . The real $[J(\omega_I)]$ and imaginary $[L(\omega_I)]$ components of the complex spectral density, $G(\omega_I)$, as well as the zero-frequency or adiabatic term $[J(0)]$, are shown. The plateau values of $J(0)$ and $L(\omega_I)$ are $|\mathcal{F}|$ and $|\mathcal{F}|^2/\omega_I$, respectively

coupling constant. If dynamic frequency shifts are considered, these transitions occur at the modified frequencies

$$\begin{aligned} &\omega_S + (1/6)L_0^{DIS}(\omega_S - \omega_I) + (1/2)L_1^{DIS}(\omega_S) \\ &+ L_2^{DIS}(\omega_S + \omega_I) + 2L_1^{SAI}(\omega_S) \\ &\pm (1/2)[J + 4L_1^{DIS,SAI}(\omega_S) + 4L_1^{DIS,SAI}(\omega_I)] \quad (11) \end{aligned}$$

$$\begin{aligned} &\omega_I + (1/6)L_0^{DIS}(\omega_I - \omega_S) + (1/2)L_1^{DIS}(\omega_I) \\ &+ L_2^{DIS}(\omega_S + \omega_I) + 2L_1^{SAI}(\omega_I) \\ &\pm (1/2)[J + 4L_1^{DIS,SAI}(\omega_S) + 4L_1^{DIS,SAI}(\omega_I)] \quad (12) \end{aligned}$$

Notice that the splitting between the two components of each doublet, $[J + 4L_1^{DIS,SAI}(\omega_S) + 4L_1^{DIS,SAI}(\omega_I)]$, is modified by cross-correlation terms. The shifts identified with the auto-correlation spectral densities affect both doublet components equally.

Similarly, the double and zero quantum transition frequencies are

$$\begin{aligned} &(\omega_I + \omega_S) + (1/2)[(L_1^{DIS}(\omega_S) + L_1^{DIS}(\omega_I)) + 2L_2^{DIS}(\omega_I + \omega_S) \\ &+ 2[L_1^{SAI}(\omega_S) + L_1^{SAI}(\omega_I)]] \quad (13) \end{aligned}$$

and

$$\begin{aligned} &(\omega_I - \omega_S) + (1/2)[(L_1^{DIS}(\omega_I) - L_1^{DIS}(\omega_S)) \\ &+ (1/3)L_0^{DIS}(\omega_I - \omega_S) \\ &+ 2[L_1^{SAI}(\omega_I) - L_1^{SAI}(\omega_S)]] \quad (14) \end{aligned}$$

Neither the zero nor double quantum coherences are dephased by adiabatic dipolar contributions. Hence, if extreme narrowing fails, the dynamic frequency shift may be *larger* than the homogeneous linewidth of either of these coherences. However, this is somewhat academic. For example, in a homonuclear spin system ($\omega_I \simeq \omega_S$), the zero quantum dynamic frequency shift is vanishingly small whereas the maximum dipole-dipole induced dynamic frequency shift of the double quantum coherence, $(\frac{3}{5})[\gamma_I\gamma_S\hbar(r_{IS})^{-3}]^2/\omega_I$, is typically less than 1 Hz.

4.2 The Three Identical Spin- $\frac{1}{2}$ System

Although differential dynamic frequency shifts between the various transitions in this important spin grouping have been noticed by many workers, few researchers have attempted to exploit this fact.⁹

For three identical spin- $\frac{1}{2}$ nuclei (I, I', I'') relaxed by mutual dipole-dipole and shielding anisotropy interactions, the dynamic frequency shifts of the three single quantum coherences within the quartet manifold are

$$\begin{aligned} \Omega_{3/2,1/2} = &-[L_1^{D_{II'}}(\omega_I) + 5L_1^{D_{II'},D_{II''}}(\omega_I) + 2L_2^{D_{II'}}(2\omega_I) \\ &- 2L_2^{D_{II'},D_{II''}}(2\omega_I) + 2L_1^{SAI}(\omega_I) \\ &- 12L_1^{D_{II'},SAI}(\omega_I)] \quad (15) \end{aligned}$$

$$\begin{aligned} \Omega_{-1/2,-3/2} = &-[L_1^{D_{II'}}(\omega_I) + 5L_1^{D_{II'},D_{II''}}(\omega_I) \\ &+ 2L_2^{D_{II'}}(2\omega_I) - 2L_2^{D_{II'},D_{II''}}(2\omega_I) \\ &+ 2L_1^{SAI}(\omega_I) + 12L_1^{D_{II'},SAI}(\omega_I)] \quad (16) \end{aligned}$$

$$\begin{aligned} \Omega_{(1/2,-1/2)_{3/2}} = &-[L_1^{D_{II'}}(\omega_I) - 7L_1^{D_{II'},D_{II''}}(\omega_I) + 2L_2^{D_{II'}}(2\omega_I) \\ &+ 4L_2^{D_{II'},D_{II''}}(2\omega_I) + 2L_1^{SAI}(\omega_I) \\ &+ 4L_1^{D_{II'},SAI}(\omega_I) - 4L_1^{D_{II'},SAI''}(\omega_I)] \quad (17) \end{aligned}$$

The dynamic frequency shift of the doublet's doubly degenerate single quantum coherence is

$$\begin{aligned} \Omega_{(1/2,-1/2)_{1/2}} = &-[L_1^{D_{II'}}(\omega_I) - L_1^{D_{II'},D_{II''}}(\omega_I) + 2L_2^{D_{II'}}(2\omega_I) \\ &- 2L_2^{D_{II'},D_{II''}}(2\omega_I) + 2L_1^{SAI}(\omega_I) \\ &+ 2L_1^{D_{II'},SAI}(\omega_I) - 2L_1^{D_{II'},SAI''}(\omega_I)] \quad (18) \end{aligned}$$

where $L_k^{D_{II'},SAI}(\omega)$ designates the interference or cross correlation between a dipole-dipole interaction and the shielding anisotropy of one of the participating spins. Likewise, $L_k^{D_{II'},SAI''}(\omega)$ arises from the interference between a

dipole–dipole interaction and the shielding anisotropy of the spin not participating in the dipole–dipole coupling.

In the absence of cross correlation, all four of these coherences share identical dynamic frequency shifts, $-[L_1^{D_{II'}}(\omega_I) + 2L_2^{D_{II'}}(2\omega_I) + 2L_1^{SA_I}(\omega_I)]$, and the spectral degeneracy of these transitions is not removed. Conversely, in the limit of complete correlation ($L_k^{D_{II'}} = L_k^{D_{II'}, D_{II''}}$ and $L_1^{D_{II'}, SA_I} = L_1^{D_{II'}, SA_I'}$),

$$\Omega_{3/2, 1/2} = -6L_1^{D_{II'}}(\omega_I) - 2L_1^{SA_I}(\omega_I) + 12L_1^{D_{II'}, SA_I}(\omega_I) \quad (19)$$

$$\Omega_{-1/2, -3/2} = -6L_1^{D_{II'}}(\omega_I) - 2L_1^{SA_I}(\omega_I) - 12L_1^{D_{II'}, SA_I}(\omega_I) \quad (20)$$

$$\Omega_{(1/2, -1/2)_{3/2}} = 6L_1^{D_{II'}}(\omega_I) - 6L_2^{D_{II'}}(2\omega_I) - 2L_1^{SA_I}(\omega_I) \quad (21)$$

$$\Omega_{(1/2, -1/2)_{1/2}} = -2L_1^{SA_I}(\omega_I) \quad (22)$$

For commonly available magnetic field strengths, the maximum dipole–dipole induced frequency shift, $(\frac{27}{10})(\gamma_I^2 \hbar (r_{II'})^{-3})^2 / \omega_I$, between the various single quantum transition frequencies of a proton triad characterized by the geometry of a methyl group, are on the order of 2 Hz.

4.3 The $I = 1$ Spin System

For a collection of isolated $I = 1$ spins relaxed by intramolecular anisotropic shieldings and quadrupolar interactions, the dynamic frequency shifts of the two single quantum coherences are defined as

$$\Omega_{1,0} = -[2L_1^{Q_I}(\omega_I) + 4L_2^{Q_I}(2\omega_I) + 2L_1^{SA_I}(\omega_I) + 12L_1^{Q_I, SA_I}(\omega_I)] \quad (23)$$

$$\Omega_{0,-1} = -[2L_1^{Q_I}(\omega_I) + 4L_2^{Q_I}(2\omega_I) + 2L_1^{SA_I}(\omega_I) - 12L_1^{Q_I, SA_I}(\omega_I)] \quad (24)$$

Once again, it is seen that the differential dynamic frequency shift between these two coherences, given by $\Omega_{1,0} - \Omega_{0,-1} = -[24L_1^{Q_I, SA_I}(\omega_I)]$, depends only on the cross correlation between competitive relaxation pathways.

The dynamic frequency shift of the double quantum coherence is

$$\Omega_{1,-1} = -[4L_1^{Q_I}(\omega_I) + 8L_2^{Q_I}(2\omega_I) + 4L_1^{SA_I}(\omega_I)] \quad (25)$$

Interestingly, the relaxation rate of the double quantum coherence has no adiabatic quadrupolar contribution and is defined by the expression

$$(1/T_2)_{1,-1} = 4J_1^{Q_I}(\omega_I) + 8J_2^{Q_I}(2\omega_I) + (32/3)J_0^{SA_I}(\omega_I) + 4J_1^{SA_I}(\omega_I) \quad (26)$$

Once again, if extreme narrowing fails then the dynamic frequency shift will be larger than the homogeneous linewidth. The maximum dynamic frequency shift of this double quantum coherence is $(3/20)(e^2 q_I Q_I / \hbar)^2 / \omega_I$ and can easily exceed 1 kHz—even for a deuteron.

For quadrupolar nuclei, significant—and easily measured—dynamic frequency shifts can be anticipated.

5 DYNAMIC FREQUENCY SHIFTS FOR QUADRUPOLEAR NUCLEI

The constant $e^2 q_I Q_I / \hbar$ for commonly studied quadrupolar nuclei in representative electronic environments typically ranges from 0.2 to 5 MHz. Thus, dynamic frequency shifts of quadrupolar nuclei generally fall within the range of one to several hundred kHz. These are significant shifts and obviously the greatest interest in the dynamic frequency shift has arisen in the study of quadrupolar nuclei.^{10–18} However, one should be reminded that, except near the T_1 minimum, this shift is small compared with the adiabatic linewidth.

The dynamic frequency shift for the specific component $\chi_{m,m-n}$ of the n -quantum coherence for arbitrary spin (either integer or half-integer) relaxed via quadrupolar couplings is given by the expression¹⁹

$$\begin{aligned} \Omega_{m,m-n} = & \frac{2n}{I^2(2I-1)^2} \{ [4I(I+1) - 24m(m-n) - 8n^2 - 1] L_1^{Q_I} \\ & \times (\omega_I) + [-4I(I+1) + 12m(m-n) + 4n^2 + 2] L_2^{Q_I} \\ & \times (2\omega_I) \} = \frac{2n}{I^2(2I-1)^2} \{ [4I(I+1)(L_1^{Q_I}(\omega_I) - L_2^{Q_I} \\ & \times (2\omega_I)) - [L_1^{Q_I}(\omega_I) - 2L_2^{Q_I}(2\omega_I)] \\ & - 4[3m(m-n) + n^2][2L_1^{Q_I}(\omega_I) - L_2^{Q_I}(2\omega_I)] \} \end{aligned} \quad (27)$$

These expressions are valid whether or not the various transitions are well-resolved or degenerate. The dynamic frequency shifts of all transitions for half-integral spin ($1 \leq n \leq 9$; $\frac{3}{2} \leq I \leq \frac{9}{2}$) are summarized in Table 1.

In Figure 2, the dynamic frequency shifts [measured in units of $2(e^2 q_I Q_I / \hbar)^2 / 25\omega_I$] of the various transitions of an $I = \frac{5}{2}$ spin are plotted as a function of an isotropic reorientational correlation time, τ_2 (measured in units of the reciprocal Larmor frequency, ω_I). For a coupling strength $e^2 q_I Q_I / \hbar = 1$ MHz and a Larmor frequency $\omega_I / 2\pi = 80$ MHz, the ordinate has been scaled such that the dynamic frequency shift is read in kHz.

In Figure 2, the three dynamic frequency shifts, $\Omega_{3/2, -3/2}$, $\Omega_{5/2, -5/2}$ and $\Omega_{1/2, -1/2}$ have been set apart from the other shifts. For each of these transitions, the corresponding linewidth has no adiabatic contribution. Thus, in the limit where $\omega_I \tau_2 > 1$, these linewidths narrow as $\omega_I \tau_2$ increases. In this situation, the dynamic frequency shift will exceed the linewidth and the general assertion that the dynamic frequency shift is small compared with the homogeneous linewidth fails.

Table 1 Dynamic Frequency Shifts for Various Transitions of Half-Integral Spin

$n = 1$	$I = \frac{3}{2}$	$I = \frac{5}{2}$	$I = \frac{7}{2}$	$I = \frac{9}{2}$

In Figure 3, the (dynamic-frequency-shift/linewidth) ratio of various adiabatic-free transitions for $I = \frac{3}{2}$ or $I = \frac{5}{2}$ are plotted as a function of $\omega_I \tau_2$. Once again, quadrupolar relaxation is assumed. The parameter $(\Omega/T_2^{-1})_{m,-m}$ is the ratio of the dynamic frequency shift compared with the halfwidth at half-height of the coherence, $\chi_{m,-m}$. In Figure 3, only the absolute value of the dynamic frequency shift is considered. [Note that although the validity of equation (27) is independent of the secular approximation, one must be more cautious in defining a T_2 value when overlapping transitions are involved. However, since secular couplings also contain no adiabatic contribution, a well-defined linewidth parameter can be identified with the coherence $\chi_{m,-m}$ in the interesting limit when $J(0) \gg J(\omega_I)$]

As mentioned earlier, the second-order dynamic and static frequency shifts are different manifestations of the same phenomenon. This is illustrated by comparing expressions for the static, second-order quadrupolar shift of a single quantum coherence $\chi_{m,m-1}$ ²⁰

$$\begin{aligned}
 & (3/16) \frac{(e^2 q_I Q_I / \hbar)^2}{I^2 (2I - 1)^2} (\omega_I)^{-1} \{ [4I(I + 1) - 24m(m - 1) - 9] \\
 & \times \langle \frac{3}{2} \sin^2 \theta \cos^2 \theta \rangle + \\
 & [-2I(I + 1) + 6m(m - 1) + 3] \langle \frac{3}{8} \sin^4 \theta \rangle \} \quad (28)
 \end{aligned}$$

with equation (27).

In the motionally narrowed limit, the isotropically averaged angular terms appearing in equation (28) each reduce to $\frac{1}{5}$ which reproduces equation (27) in the limit where $L_1^{Q_I}(\omega_I) = 2L_2^{Q_I}(2\omega_I) = (\frac{3}{160})(e^2 q_I Q_I / \hbar)^2 / \omega_I$.

Although uncommon, couplings other than the electric quadrupolar coupling may play a role in relaxing high-spin nuclei. Dynamic frequency shifts associated with these competitive relaxation pathways should not be forgotten. For example, the dynamic frequency shift for the specific

Figure 2 Plot of the quadrupole-induced dynamic frequency shifts of an $I = 5/2$ spin versus the isotropic, reorientational correlation time, τ_2 . The three coherences lacking adiabatic linewidth contributions are shown by dotted curves. The ordering of the curves in the limit $\omega_I\tau_2 \gg 1$ is as follows: $\Omega_{1/2, -1/2} > \Omega_{3/2, -3/2} > \Omega_{3/2, -1/2} > \Omega_{3/2, 1/2} > \Omega_{5/2, -1/2} > \Omega_{5/2, -3/2} > \Omega_{5/2, 3/2} > \Omega_{5/2, 1/2} > \Omega_{5/2, -5/2} > \dots$. For a quadrupolar coupling (e^2qIQ_I/h) equal to 1 MHz and a Larmor frequency $\omega_I/2\pi = 80$ MHz, the dynamic frequency shift can be read directly in kHz

component $\chi_{m, m-n}$ of the n -quantum coherence, relaxed via shielding anisotropy, is given by the expression

$$\Omega_{m, m-n} = -2nL_1^{SA_I}(\omega_I) \quad (29)$$

More importantly, the dynamic frequency shift associated with the cross correlation between quadrupolar and other interactions can be significant even when quadrupolar interactions dominate. For the case of interference between quadrupolar and shielding anisotropy, the dynamic frequency shifts are given by the expression

$$\Omega_{m, m-n} = \left[\frac{-12n(2m-n)}{I(2I-1)} L_1^{Q_I, SA_I}(\omega_I) \right] \quad (30)$$

Whereas both quadrupolar and shielding anisotropy interactions shift the pair of spin inverted coherences $\chi_{m, m-n}$ and $\chi_{-m+n, -m}$ by like amounts, interference terms shift these two coherences apart. Equation (30) demonstrates that $Q_I - SA_I$ interferences cannot effect any coherence between two spin-inverted states. Thus, unlike dynamic frequency shifts induced by quadrupole interactions alone, $Q_I - SA_I$ cross correlation does not shift any coherence lacking an adiabatic linewidth contribution.

Figure 3 Plot of the quadrupole-induced dynamic frequency shift $\Omega_{m, m'}$, measured in units of $(1/T_2)_{m, m'}$ for various coherences having no adiabatic linewidth contribution. The parameter ΩT_2 equals the dynamic-frequency-shift/halfwidth-at-halfheight ratio. Only the magnitude and not the sign of the shift is considered. The ordering of the curves in the limit $\omega_I\tau_2 > 1$ is as follows: $\Omega_{3/2, -3/2} (I = \frac{3}{2}) > \Omega_{5/2, -5/2} (I = \frac{5}{2}) > \Omega_{1/2, -1/2} (I = \frac{3}{2}) > \Omega_{1/2, -1/2} (I = \frac{5}{2}) > \Omega_{3/2, -3/2} (I = \frac{5}{2})$. The two solid curves distinguish the dynamic frequency shifts of an $I = 3/2$ spin

Efficiently relaxed quadrupolar nuclei can effectively dissipate the single quantum coherences of coupled spin- $\frac{1}{2}$ nuclei (scalar relaxation of the second kind), and through interferences with direct or indirect dipole-dipole interactions²¹ can induce dramatic dynamic frequency shifts of these same single quantum coherences.

To appreciate the basis of this phenomenon, consider the scalar coupled two-spin system where spin $S = \frac{1}{2}$ and spin $I > \frac{1}{2}$. Assume that the relaxation of spin I is effected by an axially symmetric quadrupolar interaction ($\hat{\mathcal{F}}^{Q_I}$). Spin S is relaxed directly by an $I-S$ dipolar interaction ($\hat{\mathcal{F}}^{D_{IS}}$). It is assumed that $|\hat{\mathcal{F}}^{Q_I}| \gg |\hat{\mathcal{F}}^{D_{IS}}|$. (Spin I) quadrupole-(spin I or S) anisotropic shielding interferences result in no second-order dynamic frequency shifts of spin- S single quantum coherence.

In the limit where all multiplet components are well-resolved, the S multiplet, $\mathfrak{S}(\omega)$, is described as a simple sum of $2I + 1$ Lorentzians,

$$\mathfrak{S}(\omega) = \sum_{m=-I}^I (1/T_2)_{(I, m)} / [(\omega_S - \omega - mJ + \Omega_{(I, m)})^2 + (1/T_2)_{(I, m)}^2] \quad (31)$$

where J is the I - S scalar coupling constant and ω_S is the Larmor frequency of spin S . The relaxation rate, $(1/T_2)_{(I,m)}$, and dynamic frequency shift, $\Omega_{(I,m)}$, are defined as

$$\begin{aligned} (1/T_2)_{(I,m)} = & \left[\frac{2}{I(2I-1)} \right]^2 \{ [I(I+1)(4m^2+1) - m^2(4m^2+5)] \\ & \times J^{Q_I}(\omega_I) \\ & + [(I(I+1) - (m^2+1))^2 + 3m^2 - 1] J^{Q_I}(2\omega_I) \} \\ & + (8m^2\sqrt{3}) J^{D_{IS}}(0) \end{aligned} \quad (32)$$

$$\Omega_{(I,m)} = \left[\frac{4}{I(2I-1)} \right] [I(I+1) - 3m^2] L^{Q_I, D_{IS}}(\omega_I) \quad (33)$$

Only adiabatic, dipole-dipole contributions have been included in equation (32). Although the quadrupolar interaction generally determines the linewidths of the $2I+1$ members of the S multiplet, there is no adiabatic quadrupolar contribution. Thus, in the regime where $\omega_I\tau_2 \gg 1$, the S multiplet may be characterized by anomalously narrow components exhibiting relatively large, easily measured, second-order dynamic frequency shifts. In Figure 4, simulated ^{13}C spectra of the ^{13}C - ^2H spin system, using standard interaction constants illustrate the relative magnitude of these second order shifts.²¹

6 SUMMARY

The dynamic frequency shift is a second-order effect that arises from the basic noncommutivity of the Zeeman

interaction with other spin interactions such as dipole-dipole, quadrupolar, or anisotropic shieldings. In the high-field limit, dynamic frequency shifts become less important with increasing field strength.

Usually, dynamic frequency shifts are detectable only in the vicinity of the T_1 minimum. In this region, the shift is on the order of the homogeneous linewidth. In general, motional anisotropy will diminish the relative importance of the dynamic frequency shift.

Since maximal dynamic frequency shifts are on the order of $|\mathcal{F}|^2/\mathcal{E}$ in high-field NMR, only quadrupolar interactions will induce shifts larger than a few Hz. More importantly, the linewidths associated with the coherence between spin-inverted pairs of states have no adiabatic contribution (assuming quadrupole relaxation). For these coherences, the dynamic frequency shift, no longer hidden within the linewidth, surfaces as the dominant relaxation parameter. Furthermore, interference (cross correlation) of dipole-dipole and quadrupole interactions can result in visually dramatic second-order NMR frequency shifts for spin- $\frac{1}{2}$ nuclei which are scalar coupled to quadrupolar nuclei.

1 INTRODUCTION

The application of NMR relaxation as a probe of molecule and molecular group motion in solids has provided a wealth of dynamical information and some important insights as to the nature of intra- and intermolecular barriers to rotation. Of special interest have been solids where the internal rotations of symmetrical molecular groups such as $-\text{NH}_4^+$, $-\text{CH}_3$, etc., lead to macroscopic quantum effects at low temperatures.¹ Whereas at high temperatures the reorientation dynamics can be described by incoherent thermally activated processes (classical diffusion or jumps), at sufficiently low temperatures the motion becomes a coherent quantum tunneling. Since the motion has the effect of interchanging spatial coordinates of identical particles, the requirements of the Exclusion Principle must be taken into account. Thus for molecules containing methyl groups, indistinguishability of the protons leads to observable quantum effects such as the thermally-induced dynamic spin polarization process described below. This is a consequence of a coupled spin and rotational relaxation processes, dynamically linking the observable spin magnetization to the angular momentum of the methyl group.

There are only two known cases where thermally-induced spin polarization has been observed in pure solids.^{2,3} This was first reported by Haupt in 1971 for 4-methylpyridine.² Haupt discovered that at low temperatures, a large polarization or ordering of the methyl protons with respect to the proton–proton dipolar local field occurs after a change in temperature of the solid. The polarization persists up to several hours depending on the temperature and is associated with a slow relaxation coupled to the interconversion of the proton spin species $I = \frac{3}{2}$ and $I = \frac{1}{2}$. The magnitude and duration of the Haupt effect is critically dependent on the

magnitude and symmetry of the potential function describing the barrier to one-dimensional rotation. In general, free or nearly free rotation of the methyl group about its symmetry axis is required, a situation rarely found in molecular solids. Typically, the barrier height is found to greatly exceed the methyl group rotational constant $B/k = 7.56$ K and the motion is more characteristic of tunneling between equivalent potential wells. Nevertheless it is possible to prepare solids artificially in which an impurity molecule containing a methyl group is subject to a relatively low hindering barrier using the technique of matrix isolation.

Since the technique of trapping atoms and molecules in solid rare gas matrices was first introduced,⁴ it has been applied to a wide range of questions regarding the chemistry and physics of molecules.⁵ Most of the studies have focused on molecular and electronic structure determinations of trapped atoms, stable molecules, aggregates, reactive species, and other reaction products, as well as the exploration of the nature of the matrix environment including the interactions of the impurity molecule with the rare gas lattice. The structural probes have included optical absorption, Raman, electron spin resonance (ESR)⁵ and, more recently, nuclear magnetic resonance (NMR)^{6,7} and inelastic neutron scattering (INS).⁸ The NMR of matrix isolated molecules has been especially useful in probing reorientational dynamics,⁹ in particular of methyl groups in matrices.¹⁰ From the proton NMR line shapes of molecules having the structure CH_3X where X is a linear substituent such as $-\text{C}\equiv\text{N}$, $-\text{C}\equiv\text{CH}$, or a halide, it is evident that the symmetry axis is essentially fixed in the rare gas lattice, while rotation about this axis is only weakly hindered. This is illustrated by the comparison of proton spectra of matrix isolated CH_3CCl_3 , CH_3CN , and CH_4 in Figure 1. The bottom trace shows a single narrow line for CH_4 due to isotropic reorientation in the matrix.¹¹ For CH_3CN , the molecule is sufficiently large that the molecular axis is fixed in a cavity or lattice site of the matrix, but the barrier to rotation about this axis is small.¹⁰ This is not the case for CH_3CCl_3 which has a large intramolecular barrier to rotation of the methyl group. The observed spectrum¹² is identical to the theoretical spectrum of a stationary triangle of spin $I = \frac{1}{2}$ nuclei.¹³ The intermediate case proves to be the most interesting as the molecule exhibits all the features of a fixed-axis rotator in well-defined rotational states at low temperatures.¹⁴ This is substantiated by an intense Haupt effect observed for CH_3X molecules in matrices.¹⁵

The spatial and magnetic isolation of methyl molecules achieved with matrix isolation provides a unique opportunity for a detailed exploration of the mechanism leading to spin polarization that is not possible in pure solids. Isolation suppresses intermolecular dipolar couplings so that spin ordering takes place with respect to the *intramolecular* dipolar local field. Experimentally this leads to well-resolved spectral features (see Figure 1) normally obscured due to the intermolecular dipolar broadening. This permits the observation of anisotropy in the polarization process and, more importantly, has led to the discovery of spin ordering with respect to two additional local fields. One of these is associated with heteronuclear dipolar coupling between the methyl protons and another spin in the molecule.¹⁶ The other corresponds to the molecular magnetic field arising from the rotation of nuclear and electronic charges.¹⁷ The lineshape associated with the latter spin order has revealed for the first

Figure 1 Proton NMR lineshapes of matrix isolated molecules at 5 K. (a) CH_3CCl_3 , no rotation. (b) CH_3CN , anisotropic rotation about symmetry axis. (c) CH_4 , isotropic rotation

time spin-rotation fine structure in the NMR spectrum of a solid.¹⁷ Essentially the fine structure is due to the fact that the angular momentum of the methyl group is sufficiently large in magnitude and fixed in direction so the full tensorial character of the spin-rotation interaction is preserved.

Matrix isolation also introduces a considerable simplification in the interpretation of the experimental results. The spin Hamiltonian, treated as a quantum mechanical operator in both spin and spatial coordinates, need only include *intramolecular* couplings, and it is possible to treat the rotation of each methyl group independently. To a good approximation, the methyl groups couple independently to a phonon bath provided by the rare gas lattice, with the nuclear spins interacting only indirectly with the phonon bath via the spatial part of the methyl group state function. Using this framework and the assumption of free rotation in the matrix, a theoretical basis for spin polarization with respect to local fields within the methyl group is presented below. These fields are identified as the proton-proton dipolar (II), heteronuclear dipolar (IS), and spin-rotation (IJ), each of which corresponds to a spin energy reservoir dynamically coupled to the rotational relaxation of the methyl group. The theory is shown to be consistent with NMR lineshapes recorded during the evolution of the polarization.

The assumption of free methyl rotation in the solid rare gas matrix, while useful in the discussion of rotational relaxation, is clearly an oversimplification. Indeed optical and

INS studies have shown that the unannealed matrix is a highly disordered structure which is characterized by a distribution of trapping sites. Remarkably however, the spin polarizations process is site-selective.^{15,17} Thermal annealing, which more or less tends to produce spatial site uniformity by matrix reconstruction, tends to destroy the polarization. In the last section, we explore this issue in more detail.

2 METHYL GROUP ROTATIONAL AND SPIN LEVELS

Our model for a matrix isolated symmetric top molecule CH_3X , where X is a linear substituent, is one where the symmetry axis is fixed while the molecule is free to rotate about this axis, a motion equivalent to the free rotation of a methyl group. This motion can be described by the one-dimensional Hamiltonian

$$\hat{\mathcal{H}}_R = -B \frac{\partial^2}{\partial \phi^2} \quad (1)$$

where B is the rotational constant and ϕ is the rotational coordinate describing the motion of the protons in the plane perpendicular to the fixed axis. The rotational states and energies are $\psi_R = (2\pi)^{-1/2} \exp(ir\phi)$; $E_R = r^2 B$, where $r = 0, \pm 1, \pm 2, \dots$. These states can be classified according to the three one-dimensional irreducible representations of the C_3 symmetry group $\lambda = A, E^a, E^b$. States with $r = 0, \pm 3, \pm 6, \dots$ belong to the A representation, $r = -1, 2, -4, 5, \dots$ to E^a , and $r = 1, -2, 4, -5, \dots$ to E^b .

Neglecting the small chemical shift interaction of methyl protons, we write the spin Hamiltonian for a methyl group as the sum of Zeeman ($I\mathcal{Z}$), dipolar (II), and spin-rotation (IJ) interactions:

$$\hat{\mathcal{H}}_s = \hat{\mathcal{H}}_{I\mathcal{Z}} + \hat{\mathcal{H}}_{II} + \hat{\mathcal{H}}_{II}(t) + \hat{\mathcal{H}}_{IJ} \quad (2)$$

where

$$\hat{\mathcal{H}}_{I\mathcal{Z}} = -\omega_{0I} \sum_i \hat{I}_Z^i = -\omega_{0I} \hat{I}_Z \quad (2a)$$

and

$$\hat{\mathcal{H}}_{II} = \frac{4}{3}\omega_D \sum_{i < j} \left[\hat{I}_Z^i \hat{I}_Z^j - \frac{1}{4}(\hat{I}_+^i \hat{I}_-^j + \hat{I}_-^i \hat{I}_+^j) \right] \quad (2b)$$

where $\omega_D = (\kappa/2) (1 - 3 \cos^2 \psi)$, $\kappa = \frac{3}{4} \gamma_I^2 \hbar / R_1^3 = 15.1 \text{ kHz}$, ω_{0I} is the proton Larmor frequency, γ_I the proton magnetogyric ratio, and R_1 the proton-proton distance. The angle ψ defines the orientation of the methyl group axis with respect to the external magnetic field as depicted in Figure 2. Terms of the dipolar interaction depending explicitly on time are grouped into $\hat{\mathcal{H}}_{II}(t)$. These terms are responsible for the relaxation of spin and rotational level populations. The secular terms (those that commute with $\hat{\mathcal{H}}_Z$) represented by $\hat{\mathcal{H}}_{II}$ have been written in the motionally narrowed limit corresponding to anisotropic free rotation about the methyl axis.

Figure 2 Molecular reference frame (x, y, z) of a methyl group relative to laboratory frame (X, Y, Z)

Setting aside for the moment $\hat{\mathcal{H}}_{IJ}$, the spin basis functions may be chosen as eigenfunctions of $\hat{\mathcal{H}}_{IZ} + \hat{\mathcal{H}}_{II}$. These functions are well known and have been listed in Table 1.¹⁸ The eight spin functions are labeled with the corresponding irreducible representation of symmetry group C_3 and eigenvalue with respect to I_z ($m = \pm\frac{1}{2}, \pm\frac{3}{2}$).

Table 1 Spin Eigenfunctions

$A_{3/2} = \alpha\alpha\alpha$
$A_{1/2} = 3^{-1/2}(\alpha\alpha\beta + \alpha\beta\alpha + \beta\alpha\alpha)$
$A_{1/2} = 3^{-1/2}(\alpha\beta\beta + \beta\alpha\beta + \beta\beta\alpha)$
$A_{3/2} = \beta\beta\beta$
$E_{1/2}^a = 3^{-1/2}(\alpha\alpha\beta + \epsilon\alpha\beta\alpha + \epsilon^*\beta\alpha\alpha)$
$E_{1/2}^a = 3^{-1/2}(\beta\beta\alpha + \epsilon\beta\alpha\beta + \epsilon^*\alpha\beta\beta)$
$E_{1/2}^b = 3^{-1/2}(\alpha\alpha\beta + \epsilon^*\alpha\beta\alpha + \epsilon\beta\alpha\alpha)$
$E_{1/2}^b = 3^{-1/2}(\beta\beta\alpha + \epsilon^*\beta\alpha\beta + \epsilon\alpha\beta\beta)$
$\epsilon = \exp(i2\pi/3)$

The Exclusion Principle requires that the state function be antisymmetric with respect to permutation of any two identical protons. The feasible symmetry operation for a methyl group however is a rotation by 120° , an operation equivalent to a double permutation of the spins. Thus the total state for the methyl group need only be symmetrized with respect to C_3 rotation which is equivalent to two permutations of identical particles. The allowed spin and rotation combinations are then given by

$$A_r \times A_m, \quad E_r^a \times E_m^b, \quad E_r^b \times E_m^a \quad (2c)$$

Taking these restrictions into account, the energy levels are shown in Figure 3. Only the five lowest rotational levels are included as higher levels are not significantly populated below 50 K. The eigenstates are labeled by symmetry A , E^a , or E^b . The doubly degenerate E rotational levels are shown as double lines. The Zeeman interaction $\hat{\mathcal{H}}_{IZ}$ splits the A_0 rotational level into a quartet of spin levels and the E levels into doublets. The

Figure 3 Methyl group rotational and spin energies. The columns from left to right indicate rotational levels, Zeeman, proton–proton dipolar, and spin–rotation splittings. Thermal averaging of the spin–rotation coupling due to the dashed transitions results in the cumulative splittings in the last column. The solid transitions represent relaxation through $\hat{\mathcal{H}}_{IJ}(t)$

dipolar interaction $\hat{\mathcal{H}}_{II}$ shifts the A spin levels by $+\omega_D\hbar$ but does not affect the E spin levels.

Having identified a basis set of spin and rotational functions, the spin–rotation interaction can now be considered. The general form of this coupling, given in the molecular reference frame, is

$$\hat{\mathcal{H}}_{IJ} = \sum_i \mathbf{I}^i \cdot \mathbf{C}^i \cdot \mathbf{J} \quad (3)$$

where $\mathbf{C}^i$ is a Cartesian tensor and $\mathbf{J}$ is the angular momentum of the methyl group. Transforming to the laboratory frame and retaining only terms that commute with $\hat{\mathcal{H}}_{IZ}$, equation (3) becomes for the case of anisotropic motion restricted to free rotation about the methyl axis,¹⁹

$$\hat{\mathcal{H}}_{IJ} = C_{ZZ} \cos \psi J_z I_z \quad (4)$$

where C_{zz} is the principal value of $\mathbf{C}$ along the C_3 axis. The term J_z refers to the angular momentum in the molecular frame and is thus identical to the operator $-i\hbar \partial/\partial\phi$. We note that the spin–rotation interaction contains no time-dependent

components in the laboratory frame and so does not contribute to spin or rotational relaxation.

Because the spin-rotation operator in equation (4) is diagonal in the chosen basis of rotational and spin functions, its effect on the spin states is readily evaluated and shown in Figure 3. The resulting spin level shifts depend on the expectation value of the angular momentum $\langle \hat{J}_z \rangle_r = r\hbar$. The angular momentum in the A rotational state is zero so no spin-rotation shifts occur. For the excited rotational state E_1^b (total wavefunction $E_1^b E_{\pm 1/2}^a$), the $E_{1/2}^a$ spin level is shifted by $+(C_{zz} \cos \psi)/2$ and the $E_{-1/2}^a$ by $-(C_{zz} \cos \psi)/2$. For the rotational state E_{-1}^a , the $E_{\pm 1/2}^b$ spin levels are shifted the same amounts but in opposite directions. The angular momentum for rotational states with $r = \pm 2$ is twice as large as that for $r = \pm 1$ so that the spin-rotation shifts are twice as large, as shown in Figure 3 under $\hat{H}_{IJ}$. Experimentally, however, one does observe shifts corresponding to specific rotational states, but only dynamically averaged shifts that depend on the temperature.¹⁷ The averaging results from rapid transitions between rotational states due to coupling with lattice phonons. Since this coupling contains no spin operators, the transitions can only occur among rotational levels having the same symmetry representation as indicated by the dashed lines of Figure 3. These transitions maintain a Boltzmann distribution of populations of rotational levels with a common symmetry.²⁰ The observed spin-rotation frequency shifts

$$\omega_J = \Theta \cos \psi \quad (5)$$

then represent an average over all populated levels with the same symmetry weighted by their Boltzmann factors. For the E^b rotational states, the spin-rotation constant Θ is given by the expression

$$\Theta = C_{zz} \frac{\left[\sum_r^{E^b} \langle \hat{J}_z \rangle_r e^{-(E_r - E_1)/kT} \right]}{\left[\sum_r^{E^b} e^{-(E_r - E_1)/kT} \right]} \quad (6)$$

For the E^a rotational levels, the spin-rotation shifts are in the opposite directions so that we may write an interaction that depends only on spin operators as

$$\hat{H}_{IJ} = \begin{cases} \omega_J \hat{I}_z & E^b \text{ levels} \\ -\omega_J \hat{I}_z & E^a \text{ levels} \\ 0 & A \text{ levels} \end{cases} \quad (7)$$

The thermally averaged spin-rotation shifts are shown at the far right of Figure 3. The NMR spectrum for methyl groups in A spin states will consist of three lines—one at zero frequency and a pair of lines at $\pm 2\omega_D$. For methyl groups in E states, only a pair of lines at $\pm \omega_J$ will be observed. The line spectrum corresponding to a temperature of approximately 10 K for an orientation $\psi = 70^\circ$ is shown in Figure 4. At this temperature the population of A to E rotational levels is approximately 1.9 : 1. In the matrix, the random distribution of the methyl group orientations results in a powder averaged spectrum. The theoretical unbroadened spectrum is the sum of the A and E contributions, a characteristic Pake shape over the frequency range $\pm 2\kappa$ (± 30.2 kHz), and a rectangular spin-rotation powder pattern over the range $\pm \Theta$. Since the

Figure 4 Lower trace: methyl proton transition frequencies and powder average. Upper trace: proton NMR spectrum of 0.5% CH_3/Kr matrix at 10 K

spin-rotation contribution is relatively small, temperature-dependent ($0 \leq \Theta \leq 10$ kHz, see Figure 6), and overlaps the intense zero frequency line, it is easily masked in the measured NMR spectrum of Figure 4. At 5 K and below, Θ is large and the broad rectangular powder pattern is easily lost in the dipolar powder pattern. At high temperatures, Θ becomes small and the spin-rotation contribution merges into the zero-frequency feature. It is possible using spin-echo sequences to measure the spin-rotation splitting,¹⁷ but the measurement can be carried out far more easily during a dynamic polarization experiment as described in the next section.

3 HOMONUCLEAR DIPOLAR AND SPIN-ROTATION POLARIZATIONS

The terms $\hat{H}_{IZ}$, $\hat{H}_{II}$, and $\hat{H}_{IJ}$ of the spin Hamiltonian commute with each other and therefore may be thought of as reservoirs of spin energy each with a characteristic spin temperature. For spins in thermal equilibrium at the lattice temperature, dipolar and spin-rotation magnetizations, corresponding to net alignment of the spins with respect to dipolar and spin-rotation local fields, are extremely small. There are various methods for creating dipolar order such as the application of the Jeener-Broekaert pulse sequence²¹ or performing an adiabatic demagnetization in the rotating frame (ADRF). These methods basically involve establishing contact between dipolar and Zeeman spin reservoirs. The enhancement of methyl group dipolar and spin-rotation magnetizations through the Haupt effect also involves coupling of these magnetizations, but to a much larger reservoir namely a nonequilibrium population of rotational levels created by a sudden change in the matrix temperature.

The dynamics of this process has been described in detail by Beckmann et al.²⁰ and is summarized and extended below.

The evolution of the magnetizations is conveniently evaluated using the density operator formalism. We write the density operator as a product of rotational and spin operators^{22,23}

$$\hat{\rho} = \hat{\sigma}_s \frac{e^{-\hat{\mathcal{H}}_R/kT}}{Z} \quad (8)$$

where $\hat{\sigma}_s$ represents the spin operator and $Z = \text{Tr}_r \{ \exp(-\hat{\mathcal{H}}_R/kT) \}$. The rotational density operator written in this form (at thermal equilibrium) is only appropriate at times which are long compared with the rotational relaxation time. After a temperature jump, however, equilibration requiring spin-independent transitions (dashed lines in Figure 3) are fast but equilibration requiring symmetry conversion (solid lines in Figure 3) is very slow. It is nevertheless possible to represent the density operator after the lattice temperature is suddenly changed as before, but with the modification

$$\hat{\rho} = \hat{\sigma}_s \frac{e^{-\hat{\mathcal{H}}_R/kT_f}}{Z} e^{\beta_r \hat{\mathcal{H}}_r} = \hat{\sigma} \frac{e^{-\hat{\mathcal{H}}_R/kT_f}}{Z} \quad (9)$$

where T_f is the final temperature after the temperature jump and the operator $\hat{\mathcal{H}}_r$ is defined by its eigenvalues $\langle A_r | \hat{\mathcal{H}}_r | A_r \rangle = 1$, $\langle E_r^a | \hat{\mathcal{H}}_r | E_r^a \rangle = \langle E_r^b | \hat{\mathcal{H}}_r | E_r^b \rangle = -1$. The parameter β_r can be treated as a constant of the motion representing the inverse temperature of the energy reservoir associated with the operator $\hat{\mathcal{H}}_r$. Following the temperature jump, β_r has an initial value $\beta_r(0)$ that depends on the initial and final temperatures of the jump. Its explicit form is given by Beckmann et al. Although E^a and E^b levels are independent, they have the same energies and populations. Thus β_r represents the departure of the populations E and A from equilibrium. Its value decreases to zero through the relaxing transitions as the equilibrium is established.

Because A and E spin states are restricted to A and E rotational states, $\hat{\mathcal{H}}_r$ may be considered as a spin operator and included in the spin density operator $\hat{\sigma}$ as has been done in equation (9). In the high-temperature limit, $\hat{\sigma}$ can be written as

$$\hat{\sigma} = 1 + \beta_r \hat{\mathcal{H}}_r - \beta_{IZ} H_{IZ} - \beta_{II} \hat{\mathcal{H}}_{II} - \beta_{IJ} \hat{\mathcal{H}}_{IJ} \quad (10)$$

The time dependence of the β quantities can be calculated from the master equation²³

$$\frac{d\rho_{rm}}{dt} = \sum_{r'm'} W_{r'm',rm} (\rho_{r'm'} - \rho_{r'm'}^{\text{eq}}) \quad (11)$$

Summing over r , this becomes

$$\frac{d\sigma_m}{dt} = \sum_{r,r',m'} W_{r'm',rm} \frac{e^{-\langle \hat{\mathcal{H}}_R \rangle_{r'}/kT_p}}{Z} (\sigma_{m'} - \sigma_{m'}^{\text{eq}}) \quad (12)$$

with

$$W_{r'm',rm} = \int_{-\infty}^{\infty} \langle r'm' | \hat{\mathcal{H}}_{II}(t) | rm \rangle \langle rm | \hat{\mathcal{H}}_{II}(t + \tau) | r'm' \rangle \times e^{-\omega_{rr'}\tau} d\tau \quad (12a)$$

and

$$\hat{\mathcal{H}}_{II}(t) = \frac{1}{3} \sum_{\lambda} \sum_{i=-2}^2 (-1)^i A_{2,i}(\lambda) \hat{T}_{2,-i}(\lambda^*) \quad (12b)$$

where the time-dependent dipolar interaction has been written in a symmetry-adapted form convenient for calculating the spin matrix elements. The terms of $\hat{\mathcal{H}}_{II}(t)$ have been written explicitly by Haupt.¹ Separating the spin matrix elements $K_{mm'} = \langle m | \hat{T}_{2,-i} | m' \rangle$ and making the usual assumption that the autocorrelation function is random in time and decays exponentially with a characteristic decay time τ_c , we see that

$$\frac{d\sigma_m}{dt} = \sum_{m'} K_{m,m'}^2 F_2(\sigma_{m'} - \sigma_{m'}^{\text{eq}}) \quad (13)$$

where

$$F_n = \sum_{r,r'} |\langle r | 2 \cos(n\phi) | r' \rangle|^2 \frac{\tau_c}{1 + \omega_{r,r'}^2 \tau_c^2} \frac{e^{-\langle \hat{\mathcal{H}}_R \rangle_{r'}/kT_f}}{Z} \quad (13a)$$

includes the spectral density function. We note that F_2 , the transition probability, depends on $\cos(2\phi)$ which in the limit of free rotation imposes a rotational selection rule of $\Delta r = \pm 2$. The spin transition probabilities, $K_{mm'}$, are nonzero only for $A \leftrightarrow E^a$ and $A \leftrightarrow E^b$ transitions, so that the allowed spin and rotational transitions are restricted to $\Delta r = \pm 2$, $\Delta m = 0, \pm 1, \pm 2$. Of the 12 allowed transitions, only four are shown as the vertical solid lines in Figure 3. In the case of hindered rotation, both $\Delta r = \pm 2$ and $\Delta r = \pm 1$ transitions are allowed and the relaxation is much faster due to a larger spectral density function.

The evolution of the k th spin temperature with time can be calculated using

$$\begin{aligned} \frac{d\beta_k}{dt} &= \text{Tr} \left[\hat{\mathcal{H}}_k \frac{d\sigma}{dt} \right] / \text{Tr} [\hat{\mathcal{H}}_k^2] \\ &= \sum_m \langle \hat{\mathcal{H}}_k \rangle_m \frac{d\sigma_m}{dt} / \sum_m \langle \hat{\mathcal{H}}_k \rangle_m^2 \end{aligned} \quad (14)$$

which follows from equation (10) and the orthogonality of the operators. Expressed in matrix form, the coupled evolution of the inverse spin temperatures is

$$\begin{aligned} \frac{d}{dt} \begin{bmatrix} \beta_{IZ} \\ \beta_r \\ \beta_{II} \\ \beta_{IJ} \end{bmatrix} &= - \begin{bmatrix} S_{IZ} & 0 & 0 & 0 \\ 0 & S_r & S_{r,II} & S_{r,IJ} \\ 0 & S_{II,r} & S_{II} & S_{II,IJ} \\ 0 & S_{IJ,r} & S_{IJ,II} & S_{IJ} \end{bmatrix} \\ &\times \begin{bmatrix} \beta_{IZ} - \beta_{IZ}^{\text{eq}} \\ \beta_r \\ \beta_{II} \\ \beta_{IJ} \end{bmatrix} \end{aligned} \quad (15)$$

where the the equilibrium values of β_{II} and β_{IJ} are assumed to be negligibly small. Expressions for the matrix elements of equation (15) are written explicitly in Table 2 (see below) when $\hat{\mathcal{H}}_1$ and $\hat{\mathcal{H}}_2$ are set equal to zero. A significant feature of equation (15) is that the Zeeman magnetization, proportional to β_{IZ} , is not coupled to β_I or the other inverse spin temperatures.

Table 2 Matrix Elements for Coupled Relaxation in the Heterospin Systems

$S_{IZ} = 2G(1 + 3\cos^2\psi) + 2H_1(3 - \cos^2\psi) + 2H_2(1 + \cos^2\psi)$
$S_{SZ} = 6H_1(3 - \cos^2\psi) + 6H_2(1 + \cos^2\psi)$
$zS_{IZ,SZ} = z^{-1}S_{SZ,IZ} = 4\sqrt{3}(H_1\sin^2\psi + H_2\cos^2\psi)$
$\frac{1}{2}S_r = S_{II} = S_{IJ} = 3G + 12H_1 + 6H_2$
$S_{IS} = 8H_1(2 - \cos^4\psi) + H_2(5 + 6\cos^2\psi + \cos^4\psi)$
$d^{-1}S_{r,II} = dS_{II,r} = \frac{3}{2}\sqrt{2}(1 - 3\cos^2\psi)(G - H_1 + H_2)$
$s^{-1}S_{r,IS} = sS_{IS,r} = -6\sqrt{3}(H_1\sin^2\psi + H_2\cos^2\psi)$
$j^{-1}S_{r,II} = jS_{II,r} = -3\sqrt{2}\cos\psi(G + H_1 + H_2)$
$ds^{-1}S_{II,IS} = d^{-1}sS_{IS,II} = 3\sqrt{6}(H_1\sin^2\psi + H_2\cos^2\psi)$
$dj^{-1}S_{II,IJ} = d^{-1}jS_{IJ,II} = -\frac{3}{2}G\cos\psi(1 - 3\cos^2\psi)$
$+6\cos\psi(H_1 - H_2)$
$sj^{-1}S_{IS,IJ} = s^{-1}jS_{IJ,IS} = 6\sqrt{2}\cos\psi\{4H_1(2 - \cos^2\psi)$
$+H_2(5 + \cos^2\psi)\}$
$s = \sqrt{3}\omega_s, \quad d = \omega_D/\sqrt{2}; \quad j = \omega_J/2\sqrt{2}; \quad z = \sqrt{3}\omega_{0I}/\omega_{0S}$
$G = \frac{9}{16}(\gamma_I^2\hbar/R_1^3)^2F_2$
$H_1 = \frac{3}{16}\sin^2\chi\cos^2\chi(\gamma_I\gamma_S\hbar/R_2^3)^2F_1$
$H_2 = \frac{3}{16}\sin^4\chi(\gamma_I\gamma_S\hbar/R_2^3)^2F_2$

This means that the Zeeman system is unaffected by the absence of rotational equilibrium after a temperature jump. The Zeeman magnetization does equilibrate with the lattice temperature with relaxation time T_1 , which is equal to $1/S_{IZ}$. The relaxation time for dipolar magnetization can similarly be identified with $1/S_{II}$ and the spin-rotation relaxation time with $1/S_{IJ}$.

Following a temperature jump, a nonzero value of β_r results from the deviation from equilibrium of the rotational level populations. The sign of β_r depends on whether the temperature is increased or decreased and its magnitude decays from its initial value to zero due to the $A \leftrightarrow E$ transitions. These transitions result in a net change in the dipolar and spin-rotation energies to produce a polarization of these systems. The time dependence is given by equation (15) for the coupled evolution of β_r , β_{II} , and β_{IJ} . In general, the spin magnetizations increase to a maximum after the abrupt change in temperature and then slowly decrease to their equilibrium values as illustrated in Figure 5. These curves represent the amplitude of the proton NMR signal measured at intervals following the temperature jump and are typical of the degree of polarization in matrix isolated CH_3CN .

In order to describe the time dependence of the spin magnetizations after a temperature jump, it is necessary to examine the contribution of each reservoir to the observed NMR spectrum. This consists of Zeeman, dipolar, and spin-rotation components, each having a characteristic lineshape. It is possible to separate these components using the methods described in the following. We consider the effect of a single rf pulse applied at time t after the temperature jump. If the pulse is applied along the X axis of the rotating reference frame exactly at frequency ω_{0I} , the spin-density matrix evolves under the influence of the internal Hamiltonian and it can be shown¹⁵ that the components of the FID along the X and Y axes at a time τ later are given by

$$\left. \begin{aligned} S_Y(t, \tau) &= \sin\theta\beta_{IZ}(t)\omega_{0I}\Gamma(\tau)[2 + \Lambda\cos(\omega_J\tau) + 3\cos(2\omega_D\tau)] \\ S_X(t, \tau) &= 6\sin\theta\cos\theta\Gamma(\tau)[\beta_{II}(t)\omega_D\sin(2\omega_D\tau) \\ &\quad + \sin\theta\Gamma(\tau)[\beta_{IJ}(t)\omega_J\sin(\omega_J\tau)] \end{aligned} \right\} \quad (16)$$

Figure 5 Time dependence of dipolar and spin-rotation magnetizations for a 0.2% $\text{CH}_3\text{CN}/\text{Kr}$ matrix after a $20 \rightarrow 5$ K temperature jump. (a) Dipolar intensity at $\psi = \pi/2$. The solid line is a fitted to equation (18) with $a^{-1} = 3855$ s and $b^{-1} = 510$ s. (b) Dipolar intensity at $\psi = 0$ (circles) with $a^{-1} = 5404$ s and $b^{-1} = 252$ s and spin-rotation intensity at $\psi = 0$ (triangles)

In these equations, $\Gamma(\tau)$ represents inhomogeneous damping and θ is the angle through which the magnetization is rotated by the rf field. The square brackets indicate quantities that must be powder-averaged to describe the signal in polycrystalline matrices. The quantity Λ is defined as the instantaneous ratio of E to A spinstate populations and is thus related to β_r .¹⁷ We assume Λ does not depart greatly from its thermal equilibrium value.

Equation (16) suggests that Zeeman, dipolar, and spin-rotation contributions to the signal can be separated by a suitable choice of the phase and tip angle of the rf pulse. If the reference phase of a quadrature receiver is adjusted so that the Zeeman component of the FID is obtained in the Y channel (pure absorption mode), the dipolar and spin-rotation components appear on the X channel. The Fourier transforms then give the Zeeman (cosine) or combined dipolar and spin-rotation (sine) lineshapes. The latter are shown in Figure 6 for a 0.5% $\text{CH}_3\text{CN}/\text{Kr}$ matrix for several temperature jumps with different final temperatures. These were recorded with a single 45° pulse near the maximum in the polarization. In order to obtain a selective detection of the spin-rotation lineshape, a 90° pulse need be applied. These lineshapes are also shown in Figure 6 for the same temperature jumps. Note that the width of the line varies with the temperature, the maxima and minima of the powder pattern locating the frequencies

Figure 6 Dipolar and spin-rotation spectra for 0.5% CH₃CN/Kr matrix after a temperature jump to the indicated final temperature. Left column: Overlapping dipolar and spin-rotation powder patterns following 45° pulse. Right column: Spin-rotation lines following a 90° pulse and measured values of Θ

$\pm\Theta(\psi = 0)$. A more accurate procedure for measuring Θ is to fit the spin-rotation component of the FID to the analytical function representing the powder average:

$$S_x(t, \tau, \theta = 90^\circ) = \beta_{IJ} \Gamma(\tau) (\sin \Theta \tau - \Theta \tau \cos \Theta \tau) / \Theta \tau^2 \quad (17)$$

In this procedure, the inhomogeneous linewidth is treated as a simple damping rather than convoluted with the powder pattern in the frequency domain.

The temperature dependence of the spin-rotation coupling constant, Θ , for 0.5% CH₃CN in Ar, Kr, and Xe is shown in Figure 7. The solid lines through the data were calculated using equation (9) with $C_{zz} = 9.0$ kHz and assuming free rotation in Kr and Xe but hindered rotation in Ar. The reduced angular momentum in the Ar matrix is presumably a consequence of the smaller lattice constant. From the molecular structure of the gas phase and chemical shift data, one would estimate $C_{zz} \sim 17$ kHz.¹⁷ The smaller value in the matrix is a possible indication of some motional averaging of this interaction due to wobbling of the figure axis in the rare gas lattice. This is

Figure 7 Spin-rotation coupling constant as a function of temperature for 0.5% CH₃CN in Ar, Kr, and Xe matrices. Solid lines were calculated using equation (6)

consistent with the fact that only weak spin-rotation lines are observed in matrix isolated CH₃Cl,¹⁵ a molecule with a shorter figure axis than CH₃CN or CH₃CCH. On the other hand, the failure of equation (6) to describe the spin-rotation splittings at low temperature implies that a large value of C_{zz} can only be consistent with a temperature-dependent quenching of the methyl group angular momentum. It has been suggested by Clough²⁴ that the angular momentum of the methyl group is modified by fluctuations of the surrounding lattice that are coherent with the methyl group rotation, but this, as yet, has not led to a more accurate description of spin-rotation splitting.¹⁷

It is worthwhile at this point to comment on the antisymmetric shape of the resonance lines arising from dipolar and spin-rotation magnetization. This comes about as a consequence of using the sine Fourier transform of the FID, but is ultimately due to inversion of the spin level populations during relaxation after the temperature jump. For example, the four transitions pictured at the right of Figure 3 increase the population of the $A_{\pm 3/2}$ levels relative to the $A_{\pm 1/2}$ levels, a situation corresponding to dipolar order. In the presence of the rf field, the $A_{3/2} \leftrightarrow A_{1/2}$ transition causes absorption while the $A_{-3/2} \leftrightarrow A_{-1/2}$ transition causes stimulated emission and an antisymmetric line shape overall. Similarly, spin-rotation order corresponds to a population difference of $E_{\pm 1/2}^a$ levels that is reversed for $E_{\pm 1/2}^b$ levels.

With a knowledge of the NMR lineshapes, it is now possible to consider the time evolution of dipolar and spin-rotation magnetizations after a temperature jump. From equation (15) it follows that the expressions for $\beta_{II}(t)$ and $\beta_{II}(t)$ contain three exponential terms with coefficients and rate constants found by solving cubic equations. We will not be interested in the general form, but will focus instead on two special cases representing methyl group orientations of $\psi = 0$ and $\pi/2$ with respect to the external magnetic field. Because of the isolation of the molecules in the matrix, the relaxation of methyl groups having a common orientation can be followed from the intensity of the corresponding frequency component of the powder spectrum. Considering first the case $\psi = \pi/2$, the spin-rotation splitting ω_J is equal to zero and only the dipolar magnetization is coupled to β_r . The solution of equation (15) leads to the expression

$$M_{II}(t) \propto \beta_{II} = C(e^{-at} - e^{-bt}) \quad (18)$$

with $C = \beta_r(0)S_{II,r}/(b - a)$; $a, b = \frac{1}{2}\{S_r + S_{II} \pm [(S_r - S_{II})^2 + 4S_{II,r}S_{r,II}]^{1/2}\}$.

The dipolar polarization for a 0.2% CH₃CN/Kr matrix suddenly cooled from 20 to 5 K is shown in Figure 5(a). The dipolar lineshape has been inserted to indicate the $\psi = \pi/2$ frequency component monitored during the evolution. The solid line through the points is the fit to equation (18) with rate constants given in the figure caption. These rate constants are related to the final temperature of the jump through the expressions for the $S_{k,l}$ and equation (13). The magnitude of the polarization can be estimated by comparing the sizes of Zeeman and dipolar components of the FID. For the temperature jump shown in Figure 5(a), the dipolar component at maximum polarization is on the order of 10²-times greater than the Zeeman component. For jumps to higher final temperatures, the dipolar magnetization may be 10³-times greater than the Zeeman magnetization, corresponding to $1/\beta_{II}$ in the microdegree Kelvin range. Also with increasing final temperature, the time of the decay decreases significantly from the period of hours measured for a jump to 5 K.

For orientation angle $\psi = 0$, the methyl group axis is parallel to the external magnetic field. In this case the dipolar and spin-rotation magnetizations are coupled, but the time evolutions of β_{II} and β_{II} reduce to the double exponential form of equation (18). The measured polarization curves for the 0.2% CH₃CH/Kr matrix after a 10 → 5 K temperature jump are shown in Figure 5(b). For these curves, the intensity of the $\psi = 0$ frequency components of dipolar (circles) and spin-rotation (triangles) parts of the lineshape were monitored. The solid lines were calculated using equation (18) with the indicated rate constants. Comparison of the dipolar evolution for the two methyl orientations $\psi = 0$ and $\pi/2$ in Figure 5(a) and (b) indicates that the polarization is clearly anisotropic (compare the intensities at 2 h relative to the maxima). At long times after the temperature jump, the intensities of the $\psi = 0$ and $\pi/2$ frequency components are even reversed, as shown graphically in Figure 8.

The qualitative dependence of the rate constants on orientation is that predicted theoretically. The rate constant a in equation (18), for example, is found by using Table 2 to be $a = 0$ for $\psi = 0$ and $a = 5.07$ G for $\psi = \pi/2$. These values predict that the dipolar magnetization for methyl groups at $\psi = 0$ should persist indefinitely. The observed decay is

Figure 8 Anisotropy of dipolar polarization. (a) Dipolar spectrum of 0.2% CH₃CN/Kr 30 min after a 20 → 5 K temperature jump. (b) Dipolar spectrum approximately 2 h later

due to weak interactions such as direct and indirect dipolar couplings to nitrogen and krypton nuclei which were not included in the spin Hamiltonian of equation (2). However, the large difference in rate constants as a function of orientation demonstrates the lack of a uniform dipolar spin temperature throughout the matrix. For nonisolated molecules as is usually encountered in solids, the process of spin diffusion establishes a common spin temperature and relaxation is uniform for all molecules.²³ For nominally isolated molecules as in a matrix however, a uniform spin temperature can only be assumed among methyl groups with a common dipolar splitting.

4 HETERONUCLEAR DIPOLAR POLARIZATION

In the spin Hamiltonian of equation (2), dipolar couplings between the methyl protons and other spins in the molecule were neglected. This is a good approximation for CH₃CN and CH₃CCD due to the small coupling between the protons and ¹⁴N and ²H nuclei. A relatively large coupling can be introduced, however, by labeling the molecule with an isotope with spin S in close proximity to the methyl protons. An example is ¹³CH₃CN in which the ¹³C nucleus has a spin $S = \frac{1}{2}$ and causes a resolvable splitting of the proton resonance line through the heteronuclear dipolar interaction.¹⁹ This interaction has an associated magnetization corresponding to a net alignment of the proton spins with respect to the ¹H-¹³C dipolar local field. In matrix isolated molecules undergoing

free rotation about the methyl axis at low temperatures, it is found that this heteronuclear (*IS*) dipolar magnetization is polarized at the same time as the homonuclear (*II*) dipolar and spin-rotation (*IJ*) magnetizations following a temperature jump.¹⁶ The effect, however, is not a simple extension of the analysis of the previous section because the *IS* dipolar coupling includes time-dependent terms that provide an additional mechanism for relaxation. Although the new mechanism has the same overall qualities as the *II* dipolar mechanism described in the previous section, it has unique features that provide an interesting contrast with spin polarization in unlabeled molecules and an insight into the spin polarization process in general.

The simplest form of heteronuclear dipolar coupling is obtained for a heterospin with spin $S = \frac{1}{2}$ located on the methyl group axis a short distance from the plane of the protons. The molecular frame parameters describing this spin system are shown in Figure 9. Little generality is lost as a result of this restricted geometry because only symmetric top molecules exhibit low enough barriers to methyl group rotation for the polarization process to take place. The rotational Hamiltonian for such a molecule is identical to that considered earlier, equation (1), and the spin Hamiltonian is that of equation (2) with the addition of terms representing the *S*-spin Zeeman interaction, $\hat{\mathcal{H}}_{SZ} = -\omega_S S_Z$, the secular heteronuclear dipolar interaction $\hat{\mathcal{H}}_{IS}$,

$$\hat{\mathcal{H}}_{IS} = 4\omega_s \sum_i^3 I_Z^i S_Z = 4\omega_s I_Z S_Z \quad (19)$$

and the time-dependent heteronuclear dipolar coupling, $\hat{\mathcal{H}}_{IS}(t)$. In equation (19), $\omega_s = (\eta/2) (1 - 3 \cos^2 \psi)$, $\eta = \frac{1}{4} \gamma_I \gamma_S \hbar (1 - 3 \cos^2 \chi) / R_2^3$, and γ_S is the *S*-spin magnetogyric ratio. As before, ψ is the orientation of the methyl group axis with respect to the external magnetic field direction. The Hamiltonian has been written in the motional narrowing limit as in the case of the larger *II* dipolar coupling. In order to evaluate the effect of $\hat{\mathcal{H}}_{IS}$ on the proton spin levels, a suitable choice of basis states is a simple product of *I* and *S* spin states. The *I* spin states are the set λ_{m_I} of Table 1 and the *S* spin states are the eigenfunctions of S_Z , α ($m_S = \frac{1}{2}$) and

Figure 9 Molecular frame for a methyl group and a spin $S = \frac{1}{2}$ located along the methyl axis

Figure 10 Rotational and spin levels for a methyl group coupled to a heterospin *S* excluding spin-rotation shifts. The solid lines represent transitions that produce a net *IS* dipolar polarization after a temperature jump

β ($m_S = -\frac{1}{2}$). The operator $\hat{\mathcal{H}}_{IS}$ is diagonal in this product basis and the result of the coupling is a splitting of the proton levels as depicted in Figure 10. For simplicity, spin-rotation shifts of the *E* levels are not shown.

From the selection rules $\Delta m_I = \pm 1$, $\Delta m_S = 0$, the proton NMR frequencies are located at $\pm 2\omega_S$, $2\omega_D \pm 2\omega_S$, and $-2\omega_D \pm 2\omega_S$ and are shown in the line spectrum of Figure 11(a). The powder lineshape was calculated for $^{13}\text{CH}_3\text{CN}$ using the gas phase structure,²⁴ $R_2 = 1.104 \text{ \AA}$ and $\chi = 70.5^\circ$, to give $\eta = 3.73 \text{ kHz}$. Also shown is the experimental spectrum for a 0.50% $^{13}\text{CH}_3\text{CN/Kr}$ matrix in thermal equilibrium at 5.0 K. The extra lines are due to unlabeled CH_3CN molecules in the matrix, the frequencies corresponding to the powder pattern of Figure 4.

As in the previous discussion of unlabeled carbon atoms, a nonequilibrium difference in *A* and *E* populations following a temperature jump provides the driving force for polarizing the methyl group *II* and *IJ* spin systems. With the *S* spin present, polarizing transitions are induced through the time-dependent *IS* dipolar interaction, which by analogy to equation (12) can be written as

$$\hat{\mathcal{H}}_{IS}(t) = \frac{1}{3} \sum_{\lambda} \sum_{i=-2}^2 (-1)^i \hat{B}_{2,i}(\lambda) \hat{U}_{2,-i}(\lambda^*) \quad (20)$$

where the $B_{2,i}$ and $U_{2,-i}$ operate on spatial and spin coordinates respectively. Like $\hat{\mathcal{H}}_{II}(t)$, this coupling has rotational and spin matrix elements that couple only *A* and

E states, but with two important differences. First, $\hat{\mathcal{H}}_{IS}(t)$ contains S -spin operators that provide for a polarization of the IS dipolar magnetization. The transitions that effect a net change in this magnetization are shown as the vertical lines in Figure 10. Second, the rotational selection rule is $\Delta r = \pm 1, \pm 2$, leading to two sets of transitions. Only those transitions that result in a net change in the IS magnetization are shown. At low temperatures, the spectral density function $\tau_c/(1 + \omega_{r,r'}^2 \tau_c^2)$ in equation (13a) is far larger for ω_{01} than ω_{02} , and thus the IS mechanism is the dominant relaxation mechanism for the whole system. In the case of hindered rotation about the methyl axis, $\Delta r = \pm 1$ transitions are also allowed through $\hat{\mathcal{H}}_{II}(t)$ and the two mechanisms are competitive in the relaxation.

In order to determine the coupled evolution of the rotational system and the spin magnetizations, we use the same approach as in the previous section. Included in the master equation, equation (11), is a spin-density operator that contains the additional terms corresponding to the SZ and IS spin systems. Performing the summations, we find for the time-dependence of the inverse spin temperatures

$$\frac{d}{dt} \begin{bmatrix} \beta_{IZ} \\ \beta_{SZ} \\ \beta_r \\ \beta_{II} \\ \beta_{IS} \\ \beta_{IJ} \end{bmatrix} = - \begin{bmatrix} S_{IZ} & S_{IZ,SZ} & 0 & 0 & 0 & 0 \\ S_{SZ,IZ} & S_{SZ} & 0 & 0 & 0 & 0 \\ 0 & 0 & S_r & S_{r,II} & S_{r,IS} & S_{r,IJ} \\ 0 & 0 & S_{II,r} & S_{II} & S_{II,IS} & S_{II,IJ} \\ 0 & 0 & S_{IS,r} & S_{IS,II} & S_{IS} & S_{IS,IJ} \\ 0 & 0 & S_{IJ,r} & S_{IJ,II} & S_{IJ,IS} & S_{IJ} \end{bmatrix} \begin{bmatrix} \beta_{IZ} - \beta_{IZ}^{\text{eq}} \\ \beta_{SZ} - \beta_{SZ}^{\text{eq}} \\ \beta_r \\ \beta_{II} \\ \beta_{IS} \\ \beta_{IJ} \end{bmatrix} \quad (21)$$

where the coupling matrix elements are written explicitly as in Table 2. From equation (21) we can see that the I - and S -spin Zeeman systems are coupled with each other but uncoupled from the rotational system, and thus are not polarized as the result of a temperature jump.

The coupled evolution of the rotational system and the II , IS , and IJ magnetizations lead to a complex time-dependence after a temperature jump. Qualitatively, however, the observed time-dependence of each magnetization is similar to the double exponential form seen in Figure 5. The relative contributions of each of these spin systems to the overall spin polarization can be determined by examining the proton lineshape as it evolves with time after a temperature jump. If an rf pulse applied on resonance at time t after the temperature jump rotates the magnetization through an angle θ , and if the phase of the pulse is chosen as to correspond to the X direction of the rotating frame, then the expressions for the FID detected along X and

Y directions are

$$\left. \begin{aligned} S_Y(t, \tau) &= \sin \theta \beta_{IZ}(t) \omega_{0I} \Gamma(\tau) [\cos(2\omega_s \tau) (2 + \Lambda \cos(\omega_J \tau)) \\ &\quad + 3 \cos(2\omega_D \tau)] \\ S_X(t, \tau) &= 6 \sin \theta \cos \theta \Gamma(\tau) [\beta_{II}(t) \omega_D \cos(2\omega_s \tau) \sin(2\omega_D \tau)] \\ &\quad + \sin \theta \Gamma(\tau) [\beta_{IJ}(t) \omega_J \cos(2\omega_s \tau) \sin(\omega_J \tau)] \\ &\quad + 2 \sin \theta \Gamma(\tau) [\beta_{IS}(t) \omega_s \{2 + \Lambda \cos(\omega_J \tau) \\ &\quad + 3 \cos(\omega_D \tau)\} \sin(2\omega_s \tau)] \end{aligned} \right\} \quad (22)$$

where τ is the time following the pulse. These expressions are identical to equation (16) when $\omega_s = 0$. If the reference phase of the receiver is carefully adjusted, the Zeeman component of the FID [proportional to $\beta_{IZ}(t)$] appears on the Y channel and the II , IS , and IJ components [proportional to $\beta_{II}(t)$, $\beta_{IS}(t)$, and $\beta_{IJ}(t)$, respectively] appear on the X channel. It is possible to separate the IS and IJ components of the FID from the II component by setting $\theta = 90^\circ$. The result is shown in the bottom trace of Figure 11(c) for a 0.50% $^{13}\text{CH}_3\text{CN/Kr}$ matrix 240 s after a $12.5 \rightarrow 5$ K temperature jump. This lineshape can be described exactly with only the IS component of the FID. Although equation (21) shows that the spin-rotation system is also polarized by the temperature jump, the IJ component of the FID appears to have a very low intensity and is obscured by the IS component. These spin-rotation splittings should have the same values as in Figure 7 for unlabeled CH_3CN , but are not resolved due to a further splitting by the IS coupling. The IS dipolar and spin-rotation powder lineshapes have, however, been resolved for matrix isolated $\text{CH}_3^{13}\text{CN}$ which has a smaller IS coupling constant of $\eta = 1.1$ kHz.¹¹

The characteristic lineshape for II magnetization in matrix isolated $^{13}\text{CH}_3\text{CN}$ is shown in Figure 11(b). This spectrum was recorded 30 s after a $5 \rightarrow 21$ K temperature jump by applying a $90^\circ_x \tau' 45^\circ_x$ pulse sequence with $\tau = 2$ ms. The first pulse

Figure 11 Calculated line and powder spectra for (a) Zeeman, (b) II dipolar, and (c) IS dipolar magnetizations. Bottom traces: Experimental spectra measured for a 0.5% $^{13}\text{CH}_3\text{CN/Kr}$ matrix

converts IS and IJ magnetizations to transverse magnetization while scaling the II magnetization by $-\frac{1}{2}$. After a time τ' , during which the IS and IJ magnetizations decay, the 45° pulse produces II transverse magnetization which appears on the X channel of the receiver. It is also possible to extend the acquisition so that the echo of the original IS magnetization is recorded at time τ' after the 45° pulse. In this way one can measure both β_{II} and β_{IS} simultaneously.

In Figure 11 the calculated and experimental powder lineshapes are compared. The agreement is excellent for the Zeeman and II dipolar lineshapes, but not so for the IS dipolar lineshape of (c). This difference points to an important characteristic of the $\hat{\mathcal{H}}_{IS}(t)$ polarization mechanism. Not only is there an orientation dependence in the polarization rate constants similar to that seen for the $\hat{\mathcal{H}}_{II}(t)$ mechanism in Figure 8, but also an orientation dependence in the coupling to the rotational system that has a more profound effect. This can be seen by neglecting the coupling among the II , IS , and IJ systems and focusing on the coupling of these systems with the rotational system. Using the matrix elements of Table 2, these are

$$\left. \begin{aligned} \beta_{II} &\propto S_{II,r} = (6/\kappa)(G - H_1 + H_2) \\ \beta_{IJ} &\propto S_{IJ,r} = (12/\Theta)(-G - H_1 + H_2) \\ \beta_{IS} &\propto S_{IS,r} = -(12/\eta)(H_1 \sin^2 \psi + H_2 \cos^2 \psi) \\ &\quad \times (1 - 3 \cos^2 \psi)^{-1} \end{aligned} \right\} \quad (23)$$

We see that for the II and IJ polarizations the inverse spin temperatures do not depend on the orientation of the methyl group. It is thus possible, at least in the early stages of the polarization, to factor β_{II} and β_{IJ} out of the brackets in equation (22) to calculate the lineshapes shown in Figure 11(a) and (b). But this is not true for the IS magnetization. If one treats β_{IS} as a constant in the expression for the FID, the resulting calculated lineshape of Figure 11(c) is clearly incorrect. If, however, the orientation dependence in β_{IS} shown above is included, the experimental lineshape is reproduced when $H_1/H_2 = 4.0$.^{15,16} This is again a consequence of the spatial isolation of molecules in the matrix. In interacting molecular solids after a temperature jump, rapid spin diffusion would act to establish inverse spin temperatures $\langle\beta_{II}\rangle$, $\langle\beta_{IJ}\rangle$, and $\langle\beta_{IS}\rangle$ that are uniform throughout the sample. In the matrix, the anisotropy in the polarization process is preserved and reflected in the powder lineshape. This must be taken into consideration when accounting for the time-dependence of the experimentally observed IS polarizations.¹⁵

5 THE SOLID RARE GAS MATRIX

While a great deal has been written in the scientific literature about the matrix environment in the vicinity of a trapped molecular species as obtained from optical and INS spectroscopic studies, it is worthwhile to mention some insights concerning the matrix isolation technique from spin polarization studies. The main advantage of this technique is the spatial isolation of molecules. With rare gases this is achieved by the rapid deposition of a room temperature gaseous mixture on a cold target contained in an environment

Figure 12 Schematic of experimental apparatus employed for matrix isolation NMR. The externally tuned circuit consists of a grounded single coil surrounding the sapphire sample cell and a cryogenic transmission line

free from background impurities such as atmospheric gases. With low target temperatures, ~ 4 K, and reasonably high vacuums, 10^{-6} to 10^{-7} torr, molecular aggregation can be avoided but at the expense of a highly disordered microcrystalline matrix. An adaptation of this technique for proton NMR studies²⁶ is shown in Figure 12. The hollow cylindrical (4×6 mm) sapphire sample cell is supported by a copper adapter at the tip of an Air Products Helitran and maintained at a temperature below 10 K during the matrix deposition. Unlike the thin films used in optical and IR studies, but like INS studies, the volume of the porous matrix is large, occupying one-third of the sample cell and containing approximately 10^{18} spins of interest.

Except in the case of molecules with large rotational constants, e.g., hydrogen halides, CH_4 , etc., there have been few infrared or Raman studies of hindered rotation in rare gas matrices that permit an estimation of barrier heights.^{6,27,28} Hindered rotation results in frequency shifts and the site multiplicity to inhomogeneous broadening of rotation-vibration spectra.²⁹ Employing very dilute matrices, the inhomogeneities of the initially formed matrix can be small, $1-2 \text{ cm}^{-1}$, and often reduced by matrix reconstruction on annealing (usually 50–60 K for Kr). As a result, the only characterization of the matrix from such studies is with respect to some average barrier to molecular rotation rather than details concerning site distribution.^{30,31} Only in the case of matrix isolated CH_4 , where the tendency for molecular aggregation on thermal annealing is small, do the INS studies, which require large and relatively high concentration matrices, provide direct information on site nonuniformity potential barriers to rotation.^{32,33}

After initial deposition, the matrix can best be described as a distribution of potential barriers to the rotation of methyl groups which can range from zero to several times the rotational constant B . The presence of a potential barrier to guest molecule rotation affects the proton NMR directly through the spin-rotation splitting, which depends on the methyl group angular momentum, and the degree of spin polarization after a temperature jump, which depends on the separation of the rotational levels. This introduces a *selectivity* for molecules based on their matrix environment that is uncommon among other spectroscopic methods. Following a temperature jump, only molecules in sites where the potential barrier is very low contribute to the polarization. Thus, the dipolar and spin-rotation spectra are characteristic of free rotor molecules while the Zeeman spectrum reflects the entire distribution of environments. Unfortunately, it is difficult to relate quantitatively the intensities of Zeeman and dipolar components of the FID to site occupations. It is possible, however, to compare the population of E spin states in low and high barrier sites based on the spin-rotation splitting in spin echo spectra. In an unannealed 0.5% $\text{CH}_3\text{CN/Kr}$ matrix, it is found that about one-half of the molecules occupy sites with a negligible potential barrier.¹⁷

Thermal annealing provides further insight to the matrix environment. Remarkably, the quenching of the spin polarization associated with annealing occurs at temperatures as low as 25 K in Kr and 20 K in Ar, i.e. far below the usual annealing temperatures for rare gas matrices.^{30,34} It appears that this effect is due to diffusion, which brings the guest molecules into closer proximity, because annealing also causes a concomitant increase in the thermal equilibrium linewidths and a decrease in the spin-lattice relaxation times both indicative of increased intermolecular dipolar interactions. The effect is most drastic for annealing at higher temperatures (>40 K for Kr) after which a jump to a low temperature yields a severely broadened Zeeman lineshape from the Y component of the FID and a very small but still sharp dipolar lineshape from the X component of the FID. Finally, heating matrices formed using the arrangement of Figure 12 to bulk rare gas annealing temperatures leads to such severe molecular aggregation as to eliminate any advantages of the spatial isolation that permits observation of the interesting macroscopic quantum effects described earlier.

Despite the above comments, the site distribution cannot be attributed solely to the interaction of pairs or larger clusters of guest molecules. That there is also a site dependence for isolated molecules is obvious from the spin-rotation splittings seen in Figure 7. Using the same measuring procedures, the splittings in the Ar matrix are smaller than in Kr and Xe matrices. If, as we have maintained, the splittings are characteristic of isolated molecules at sites with low barrier to rotation, the reduced splitting in Ar must be due to an increase in the potential barrier. We expect that such differences in matrix barriers to methyl rotation will prove to be a useful test for molecular dynamics calculations in solid lattices.

1 INTRODUCTION

When a person stands at the edge of a deep canyon and sharply shouts their own name, it may happen that this name, somewhat distorted, and not as loud, will come back to them after a second or so. This return of the initial signal we call an echo. We think of the opposite wall of the canyon reflecting the signal back toward us. In the jargon of NMR, we could say that a sharp signal was broadcast, something is there to 'reflect' this signal, and a somewhat attenuated and distorted response, an 'echo' of the original, is detected at a later time. There is a sense in which we might say that time has been reversed in this experience—except that, for exact time reversal, we might expect that the name would return to us spoken backwards.

One use of echoes in materials science is that in nondestructive testing on metals by sharp sonic signals. Here, a transducer is used to broadcast a pulse of sound into the solid, and the echo, received back by a detector, is used to infer voids, cracks, or general faults in the material. In this case, the echo received from the initial pulse of sound is modulated by the information from macroscopic defects in the solid, and this modulation is unwound to infer the nature of the defect. This case is almost an exact analog of the 'modulated spin echo' first reported by Hahn and Maxwell.¹ In this article, we provide an introduction to the subject of echoes in the study of solids by NMR, with specific attention to those echoes produced by the rotations of internal interactions by the radiofrequency field, B_1 . We can call these 'spin echoes'. As is discussed in *Rotating Solids* there are also echoes produced by physical rotations of the sample, e.g., by 'magic angle spinning'. We call these 'spun echoes'. In this article, we pay specific attention to the case of 'spin echoes' in solids, and their production and detection under radiofrequency excitations.

2 BASIC IDEAS

A spin echo² in NMR is quite analogous to that produced when calling one's name in a canyon. A transient transverse magnetization is created, something is done to cause this magnetization to be 'reflected' backwards, and, at a later time, this magnetization transient, somewhat attenuated, flashes back into our detector. We can then repeat the event that refocused the magnetization, and again we shall see an echo. If we are able to watch the signal on the detector, let us say an oscilloscope screen that is exhibiting the memory of a digitizer, from the moment of the broadcast of the initial signal to the return of the echo, and we repeat the refocusing event five times, we might see a signal such as that shown in Figure 1.

Figure 1 Magnetization amplitude $I(t)$ versus time t . Left, initial decay after a 90° pulse. Five echoes follow five 180° refocusing pulses

This signal is in fact a series of spin echoes when the nucleus in question is ^1H in water; the sequence used to produce this effect is the Carr–Purcell³ version of the Hahn spin echo sequence. The system is prepared with the magnetization along the y direction in the rotating frame by a 90°_x pulse, and then a series of 180° pulses, switched in phase by 90° from the preparation pulse (which is to say, along the y axis in the rotating frame), are used to produce the echoes: we designate the sequence by the shorthand notation $90^\circ_x, \tau, (180^\circ_y, 2\tau) \times 5$.

The signal shown in Figure 1 is observed with the reference phase adjusted for detection along the y axis in the rotating frame. It has a number of interesting features. First, we see a hint of the transient 90° pulse at the beginning, on the left of the figure, as the few points from the baseline up. Second, we see the free induction decay after this pulse. Then, we see a hint of the 180° pulse, and subsequently a signal 'refocusing' back up, reaching an echo maximum, and then decaying back down. This situation is repeated four more times. If we look just at the echo envelope, i.e., the maximum at the beginning of the FID, and the succeeding maxima of the echoes, we see that this envelope roughly describes something looking like an exponential decay. However, in the case shown, there is clearly an oscillation in the envelope—a modulation of the echoes. The spin echo experiment and the modulation of the echo envelope are the subjects here. Finally, we see that the envelope of the echo lasts longer than the FID itself; i.e., if we denote the decay constant for the FID by T_2^* , and the decay constant for the echo envelope by T_2 then we see that the effective decay time of the FID, T_2 , has been lengthened compared with T_2^* by the sequence of 180° refocusing pulses. A classical picture of the initial excitation and the 180° refocusing is shown in Figure 2 for a single refocusing pulse.

Figure 2 Classical picture of the spin echo: top, polarization, and 90° pulse, followed by dephasing on resonance. Bottom, 180° refocusing pulses, followed by rephasing

3 TIME-DEPENDENT QUANTUM MECHANICS OF THE SPIN ECHO

To place our discussion in perspective, it is necessary to recognize explicitly what has been implicit in the above introduction, namely, that there are two fundamental facts about NMR.

1. A nucleus with a magnetic moment proportional to a constant γ , will resonate at an angular frequency ω in a static magnetic field $\mathbf{B}$ given by $\omega = \gamma B$. The sensitivity to detection is proportional to γ , and to the natural abundance of the nucleus in question.
2. Hidden in fundamental fact 1 is the time-dependent mechanics tersely summarized in the following equations:

$$i \frac{d\hat{\rho}}{dt} = [\hat{\mathcal{H}}, \hat{\rho}] \quad (\text{energies in units of radial frequency}) \quad (1)$$

$$\langle \hat{I}_y(t) \rangle = \text{Tr} \hat{\rho}(t) \hat{I}_y \quad (2)$$

$$\hat{\rho}(t) = \hat{U}(t, 0) \hat{\rho}(0) \hat{U}^{-1}(t, 0) \quad (3)$$

Equation (1) is the time-dependent Schrödinger equation, expressed in density matrix formalism.⁴ equation (2) shows how the solution of equation (1) is used to obtain the time dependence of observables, e.g., the time decay of the magnetization of a nuclear spin system under a resonant excitation. In equation (2) detection is made along the y axis of the rotating frame. The Fourier transform of the time decay is the NMR spectrum. Implicit in equation (2) is the fact that we are using matrix representations to describe our system. $\text{Tr} \hat{A}$ denotes the trace, or sum of the diagonal elements, of the matrix representing the operator $\hat{A}$. Equation (3) indicates the formal solution of equation (1). The absolutely critical term here is the propagator $\hat{U}(t, 0)$, which drives the ensemble of

magnetically resonant nuclei under study from time zero to time t (quite a lovely introduction to the subject of propagators in quantum mechanics is given by Mattuck⁵). It is exactly an understanding of how the experimenter controls $\hat{U}(t, 0)$ that makes NMR such a powerful technique for probing the properties of inert and living matter.

4 ROTATIONS IN SPIN SPACE: SELECTIVE AVERAGING

All spectroscopy experiments implicitly or explicitly involve solutions of the time-dependent Schrödinger equation. An understanding of NMR involves at least a rudimentary knowledge of the solutions of this equation in the density operator formulation. Fortunately, there are texts for students at both the entry level^{6,7} and advanced levels⁸⁻¹⁰ presenting both of these pictures. Abragam's monumental 1961 monograph 'Principles of Nuclear Magnetism'¹¹ is still a standard reference in the field, with gems yet to be mined so long after its publication.

As a basis for understanding the spin echo experiment, we tersely summarize the results of selective averaging theory on first the result of the spin echo sequence upon an ensemble of spins $\frac{1}{2}$ in a solid, e.g., protons in solid gypsum, $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$. Here, the principal internal interactions are, in decreasing order of magnitude,

1. anisotropic shielding;
2. the homonuclear dipolar interaction.

We start in the rotating frame of the Zeeman interaction, the frame in the laboratory in which NMR signals are detected after demodulation removes the carrier frequency from the information content of the signal. In the rotating frame, the principal effective magnetic fields that cause a spin- $\frac{1}{2}$ nucleus such as a proton to resonate for detection by NMR are

1. The externally applied radiofrequency field $\mathbf{B}_1$, which is constant in the rotating frame on resonance, with, e.g., an interaction Hamiltonian for a pulse along the phase x being

$$\hat{\mathcal{H}}_1 = -\gamma B_1 \hat{I}_x = -\omega_1 \hat{I}_x \quad (4)$$

2. The sample-supplied, or internal, average of the fields associated with all other internal interactions. For non-spin- $\frac{1}{2}$ nuclei, the major interaction is the electric field gradient, which perturbs the energy levels of quadrupolar nuclei. For concentrated spin- $\frac{1}{2}$ nuclei such as ^1H and ^{19}F , the major fields are the dipolar fields of all other protons or fluorine nuclei, $\mathbf{B}_D$, in which a proton or fluorine will precess with a frequency

$$\omega_D = \gamma B_D \quad (5)$$

A smaller perturbation is the anisotropic shielding field associated with the reaction of electrons in the environment of the nucleus under observation to the externally imposed static field. With each field is associated an energy and a quantum mechanical energy operator $\hat{\mathcal{H}}$. Thus the energy operator in the rotating frame is given by

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_{\text{rf}} + \hat{\mathcal{H}}_{\text{int}} \quad (6)$$

where the magnitude of $\hat{\mathcal{H}}_{\text{rf}}$ for purposes of solid state experiments is about 5 mT. The magnitude of $\hat{\mathcal{H}}_{\text{int}}$ is never greater than a few tenths of a millitesla in the case discussed here. The equation of motion of the system is then given by the solution to equation (1) with $\hat{\mathcal{H}}$ being the sum of the rf and internal interactions, as specified in equation (6). The average values of observables, e.g., $\langle \hat{I}_y(t) \rangle$, the free induction decay detected along the y phase in the rotating frame, are given by equation (2).

With the interactions separated in magnitude in this manner, it makes sense to treat $\hat{\mathcal{H}}_{\text{int}}$ as a perturbation of $\hat{\mathcal{H}}_{\text{rf}}$. Recall that the transformation to the frame of the Zeeman interaction (the rotating frame) simplifies the description of a nuclear spin in the presence of other interactions: for example, the oscillating on-resonance rf field becomes static in the rotating frame. Similarly, transformation to the frame of the now largest interaction $\hat{\mathcal{H}}$ further simplifies the description of the system. The transformation to the frame of the rf is accomplished by the following relations:

$$\hat{\rho} = \hat{U}_{\text{rf}} \hat{\rho} \hat{U}_{\text{rf}}^{-1} \quad (7)$$

$$i \frac{d\hat{U}_{\text{rf}}}{dt} = \hat{\mathcal{H}}_{\text{rf}} \hat{U}_{\text{rf}} \quad (8)$$

$$\hat{U}_{\text{rf}}(0, 0) \equiv \hat{U}_{\text{rf}}(t=0) = \hat{1} \quad (9)$$

$$\hat{\mathcal{H}}(t) = \hat{U}_{\text{rf}}^{-1}(t, 0) \hat{\mathcal{H}} \hat{U}_{\text{rf}}(t, 0) \quad (10)$$

As mentioned above, the notation $\hat{U}(t, 0)$ is a formal way of saying that the propagator, $\hat{U}$, drives the system from time 0 to time t . An explicit operational form of $\hat{U}$ will be given below; for now, accept it as that quantity causing the system to proceed in time, with physical origin in the time-dependent sequence of rf pulses and the internal interactions as affected by these pulses. The result,

$$i \frac{d\hat{\rho}}{dt} = [\hat{\mathcal{H}}_{\text{int}}, \hat{\rho}] \quad (11)$$

where $\hat{\mathcal{H}}_{\text{int}}$ is given by equation (10), is that the motion of the system in the new frame, the frame of the rf field, now no longer explicitly contains the rf interaction (recall that transforming to the frame of the Zeeman field removed that interaction from the description of the system).

We next make a second transformation to the frame of $\hat{\mathcal{H}}_{\text{int}}$, simply reproducing equations (7)–(10) with the appropriate change in symbols:

$$\hat{\rho} = \hat{U}_{\text{int}}(t, 0) \hat{\rho} \hat{U}_{\text{int}}^{-1}(t, 0) \quad (12)$$

$$i \frac{d\hat{U}_{\text{int}}}{dt} = \hat{\mathcal{H}}_{\text{int}} \hat{U}_{\text{int}} \quad (13)$$

$$\hat{U}_{\text{int}}(0, 0) = \hat{1} \quad (14)$$

Thus $\hat{\rho}$ is replaced by $\hat{\tilde{\rho}}$, $\hat{\rho}$ is replaced by $\hat{\tilde{\rho}}$, $\hat{U}_{\text{rf}}$ is replaced by $\hat{U}_{\text{int}}$, etc. The system in this frame is static:

$$i \frac{d\hat{\tilde{\rho}}}{dt} = [0, \hat{\tilde{\rho}}] = 0 \quad (15)$$

We formally identify this static system with the system at time zero; $\hat{\rho}$ then becomes identical to $\hat{\rho}(0)$. In this perturbation picture, with $\hat{\mathcal{H}}_{\text{int}}$ being a perturbation of $\hat{\mathcal{H}}_{\text{rf}}$, the motion of the system is described by

$$\hat{\rho}(t) = \hat{U}_{\text{rf}}(t, 0) \hat{U}_{\text{int}}(t, 0) \hat{\rho}(0) \hat{U}_{\text{int}}^{-1}(t, 0) \hat{U}_{\text{rf}}^{-1}(t, 0) \quad (16)$$

5 THE AVERAGE HAMILTONIAN AND ECHOES

Before becoming explicit about the operational forms of the propagators $\hat{U}$, let us examine equation (16) more closely. It is clear that if both $\hat{U}_{\text{rf}}(t_c, 0)$ and $\hat{U}_{\text{int}}(t_c, 0)$ are unity at some particular time t_c then, at this special time, it appears that the system has simply not changed, i.e., equations (2) and (16) at time t_c , tell us that the value of any observable at this time is the value of that operator at time zero; at time t_c , $\hat{\rho}(t_c) = \hat{\rho}(0)$. There is therefore an enormous simplicity in the behavior of the system, which the experimenter may accomplish with proper arrangements of sufficiently powerful rf pulses, since both $\hat{U}_{\text{rf}}$ and $\hat{U}_{\text{int}}$ depend upon $\hat{\mathcal{H}}_{\text{Zrf}}$, the rf pulses that we supply! The fields (5 mT) generated by the rf pulses are much larger than the ‘internal fields’ due to dipolar interactions and shielding (< 0.3 mT) (but not, in general, electric field gradients on quadrupolar nuclei). That is to say, the initial broadcast of our excitation is ‘sharp’, as in the name-calling event described at the beginning of this article. In that case, if we had called our name slowly and softly compared with the background noise of the wind sighing through the trees, and the calls of the eagle circling below, we would not have received back an echo response to our call. In more mathematically explicit terms, as long as $\hat{U}_{\text{rf}}$ operates for times short compared with times in which $\hat{U}_{\text{int}}$ affects the system, its motion is predominantly controlled by $\hat{U}_{\text{rf}}$. Then, if the sequence of rf pulses generating $\hat{U}_{\text{rf}}(t_c, 0)$ returns the system to its initial state, $\hat{U}_{\text{rf}}(t_c, 0)$ is formally equal to unity—a result inferred from physics rather than mathematics. Examples of such pulse sequences are easily imagined if the physics is kept clearly in mind. One example is the sequence $(t, 180^\circ_y, \tau, 180^\circ_y, \tau)$ which results in a rotation by 2π about the y axis, leaving the system invariant at a cycle time $t_c = 3\tau$. The sequence $(\tau, 90^\circ_x, \tau, 90^\circ_y, 2\tau, 90^\circ_{-y}, \tau, 90^\circ_{-x}, \tau)$ has pairs of pulses that cancel each other (the y pulse cancels the $-y$ pulse, and similarly for x) and leave the system invariant at a cycle time $t_c = 6\tau$. Such sequences are said to be *cyclic*. If these groups of pulses are repeated periodically, they are both cyclic and *periodic*. As long as $\hat{U}_{\text{rf}}(nt_c, 0)$ is the dominant propagator, in the ‘windows’ between these groups of pulses, the system will behave as if it is not moving in time. The behavior of the system becomes refocused at these ‘echo times’ nt_c .

We have here a situation analogous to that which we might imagine if we had been able to use a strobe light to watch the glitter and dynamic flowing that was a performance by the late Janice Joplin. To see her perform at her most intense,

belting out a song like ‘Try (Just a Little Bit Harder)’, was to experience a visual sensation of watching mercury boiling. Under a strobe, however, we might have been able to recognize that her motions, which were rhythmic with the beat of the music, viewed in the windows of time periodic with these motions, would make her appear to us to be almost not moving. However, since she was not just an automaton repeating a periodic motion in sync with the strobe, we should see that nuances that were lost without the strobe now become visible. She would appear to move very slowly, in analogy to a modulated spin echo (see below). We might say that her motion appears to vary quite slowly relative to her motion when seen in the absence of a strobe. The rapid motion that we should see without a strobe has been selectively averaged to zero. In this circumstance, we are able to see details of much slower motion that we might have missed had we viewed her doing her full routine—which could be quite rapid and stunning.

6 THE MODULATED SPIN ECHO

With the performance of Janice Joplin viewed in a strobe light kept in mind, let us take a close look at equation (16). We see here that as time progresses, $\hat{U}_{\text{int}}(nt_c, 0)$ begins to affect the motion of the system. If the propagator $\hat{U}_{\text{rf}}(t, 0)$ dominates the situation at short times, meaning that the magnitude of $\hat{\mathcal{H}}_{\text{rf}}$ is much larger than the magnitude of $\hat{\mathcal{H}}_{\text{int}}$, then, as time progresses, observation in the windows nt_c will reveal some motion due to $\hat{U}_{\text{int}}(nt_c, 0)$. Now this propagator, $\hat{U}_{\text{int}}(nt_c, 0)$, is determined by $\hat{\mathcal{H}}_{\text{int}}$. The interaction $\hat{\mathcal{H}}_{\text{int}}$ in the case considered is the sum of $\hat{\mathcal{H}}_{\text{D}}$ and $\hat{\mathcal{H}}_{\text{CS}}$, the dipolar and shielding interactions as manipulated by the rf pulses. If somehow the dipolar interaction (but not the shielding interaction) can be selectively set in motion so that its time average at times nt_c is zero, the remaining information in the windows of the stroboscopic observation will be the shielding. The nuances of a Joplin performance become visible if the rapid periodic motion in time with the rhythm is selectively averaged out of our vision by using a strobe. This is exactly what multiple pulse homonuclear decoupling attempts to accomplish. To see how this works, one needs an explicit operational form for the internal propagator $\hat{U}_{\text{int}}(nt_c, 0)$. The form is illustrated with the spin echo sequence, $(\tau, 180^\circ_y, \tau, 180^\circ_y, \tau)$. In the sequence, we take the internal Hamiltonian to represent any interaction proportional to the operator $\hat{I}_z$, e.g., shielding, resonance offset, static field inhomogeneities, and scalar couplings to unlike nuclei. Homonuclear dipolar coupling, as shown below, is not simply proportional to $\hat{I}_z$.

When we manipulate $\hat{\mathcal{H}}_{\text{int}}$ by cyclic and periodic sequences of rf pulses [$\hat{U}_{\text{rf}}(nt_c, 0) = 1$] the form of the propagator $\hat{U}_{\text{int}}$ becomes an exponential (see Chapter 4 of Gerstein and Dybowski⁶), with the leading term in the result, observed at cycle times nt_c , given by

$$\begin{aligned} \hat{\rho}(nt_c) &= \hat{U}_{\text{int}}(nt_c) \hat{\rho}(0) \hat{U}_{\text{int}}^{-1}(nt_c, 0) \\ &= \exp(-i\hat{\mathcal{H}}_{\text{int}}^{(0)}) \hat{\rho}(0) \exp(i\hat{\mathcal{H}}_{\text{int}}^{(0)}) \end{aligned} \quad (17)$$

Here, $\hat{\mathcal{H}}_{\text{int}}^{(0)}$ is equal to the integral over a cycle of the internal Hamiltonian as manipulated in time by the rf pulses:

$$\hat{\mathcal{H}}_{\text{int}}^{(0)} = \frac{1}{t_c} \int_0^{t_c} \hat{\mathcal{H}}_{\text{int}}(t) dt \quad (18)$$

This time average of the internal Hamiltonian, as manipulated by the rf pulses, may be interpreted as an average internal Hamiltonian. If this time average is zero, then, for a cyclic, periodic sequence, both $\hat{U}_{\text{rf}}(nt_c)$ and $\hat{U}_{\text{int}}(nt_c)$ will be unity, and at times nt_c the system will behave as if there is nothing driving it; it will ‘echo’ its initial state in time.

The manner of manipulation of $\hat{\mathcal{H}}_{\text{int}}$ is as follows:

$$\hat{\mathcal{H}}(t) = \hat{U}_{\text{rf}}^{-1}(t, 0) \hat{\mathcal{H}}_{\text{int}} \hat{U}_{\text{rf}}(t, 0) \quad (19)$$

$\hat{\mathcal{H}}_{\text{int}}(t)$ is the *instantaneous* value of the internal Hamiltonian as determined by the rf pulses. $\hat{U}_{\text{rf}}(t, 0)$ is the propagator due to the rf pulses from time zero to time t . For n time intervals δ_1 , followed by $\delta_2, \dots$, followed by δ_n , $\hat{U}_{\text{rf}}$ is clearly the propagator during interval δ_1 , followed by the propagator during $\delta_2, \dots$:

$$\hat{U}_{\text{rf}}(t, 0) = \hat{U}_{\text{rf}}(\delta_n) \cdots \hat{U}_{\text{rf}}(\delta_1) \quad (20)$$

The inverse of this product of matrix operators is given by

$$\hat{U}_{\text{rf}}^{-1}(t, 0) = \hat{U}_{\text{rf}}^{-1}(\delta_1) \hat{U}_{\text{rf}}^{-1}(\delta_2) \cdots \hat{U}_{\text{rf}}^{-1}(\delta_n) \quad (21)$$

The physical meaning of the exponentials in equation (17) can be seen from the fact that they can always be expressed as a product of rotations in spin space acting on components of angular momentum operators. For example, consider the rf pulse sequence with perfect delta-function pulses $(\tau, 180^\circ_y, 2\tau, 180^\circ_y, \tau)$, shown in Figure 3.

This sequence is used to produce $\hat{\mathcal{H}}_{\text{rf}}$, and thus $\hat{U}_{\text{rf}}$, equal to $\exp(-i \int_0^t \hat{\mathcal{H}} dt)$, as indicated in Figure 3. At times $0 < t < \tau$ when the rf Hamiltonian is zero, $\hat{U}_{\text{rf}}(t, 0)$ takes the form $e^0 = 1$, and in this time interval the value of $\hat{I}_z$ as manipulated by the rf pulse sequence in Figure 3 is given by equation (19). We may physically identify $\hat{U}_{\text{int}}(0 < t < \tau)$ as given in equation (19) with a rotation $\hat{R}$ of unity, performed on $\hat{I}_z$, symbolized by $\hat{R}\hat{I}_z = 1 \cdot \hat{I}_z$. At time $t = \tau$, the rf Hamiltonian corresponds to an infinitely fast rotation about the y axis of 180° . $\hat{U}_{\text{rf}}(t = \tau) = \exp(i\pi\hat{I}_y)$, and the physical result is a 180°_y rotation, $\hat{R}_{180y}$, which sends the operator $\hat{I}_z$ into the operator $-\hat{I}_z$. For $\tau < t < 2\tau$ the rf again is zero, and $\hat{U}_{\text{rf}}$ is unity. At $t = 3\tau$, another 180°_y takes place. Under this sequence, therefore, with the spin portion of $\hat{\mathcal{H}}_{\text{int}}$ being proportional to $\hat{I}_z$, and keeping in mind the time ordering dictated by equations (20) and (21), we find the sequence of values of $\hat{I}_z$ in the frame of the rf pulses (see Figure 3)

$$0 < t < \tau : \hat{I}_z \rightarrow e^{-0} \hat{I}_z e^0 = 1 \cdot \hat{I}_z \cdot 1 = 1 \cdot \hat{I}_z = \hat{I}_z \quad (22a)$$

$$t = \tau : \hat{I}_z \rightarrow 1 \cdot \hat{R}_{180y} \hat{I}_z = -\hat{I}_z \quad (22b)$$

$$\tau < t < 3\tau : \hat{I}_z \rightarrow 1 \cdot \hat{R}_{180y} \cdot 1 \cdot \hat{I}_z = -\hat{I}_z \quad (22c)$$

$$3\tau < t \leq 4\tau : \hat{I}_z \rightarrow -\hat{I}_z \quad (22d)$$

Figure 3 Spin echo sequence, illustrating the pulses (square waves), the propagator associated with the pulses, $\hat{U}_{\text{rf}}(t,0)$, and the average Hamiltonian associated with an internal interaction proportional to $\hat{I}_z$

The familiar result is that at periodic cycle times $4n\tau$, under the spin echo sequence $(\tau, 180_y, 2\tau, 180_y) \times n$, chemical shifts and field inhomogeneities, with spin operators $\hat{I}_{zk}$, vanish, but other interactions, such as homonuclear dipolar coupling, do not. That is to say, at cycle times $4n\tau$, with the internal Hamiltonian being proportional to $\hat{I}_z$, $\hat{\mathcal{H}}_{\text{int}}^{(0)}$ is zero:

$$\begin{aligned} \hat{\mathcal{H}}_{\text{int}}^{(0)} &\propto \int_0^{4\tau} dt \hat{U}_{\text{rf}}^{-1}(t) \hat{\mathcal{H}}_{\text{cs}} \hat{U}_{\text{rf}}(t) \\ &= 2\omega_{\text{cs}}[\hat{I}_z\tau + (-\hat{I}_z)\tau] = 0 \end{aligned} \quad (23)$$

Here ω_{cs} is a product of a constant (ΔB_{eff}) and the part of the chemical shift Hamiltonian that is a function of the real space angular variables θ and ϕ . We may think of observation at periodic cycle times $t = 4n\tau = nt_c$ as observation in the frame of $\hat{\rho}$.

7 THE DIPOLAR ECHO AND THE FIRST-ORDER QUADRUPOLEAR ECHO

The above are the basic ideas behind the use of rf pulses to produce echoes in solids. With these ideas, it is possible to see how rf sequences may be tailored to average to zero a specific interaction, and leave other interactions for observation. Two other interactions that immediately come to mind are the homonuclear dipolar interaction and the first-order quadrupolar interaction. Both of these have interactions that are bilinear in spin operators (*Internal Spin Interactions and Rotations in Solids*). For example, the first-order quadrupolar interaction scales as

$$\hat{\mathcal{H}}_Q \propto \hat{I}^2 - 3\hat{I}_z^2 \quad (24)$$

and the two-body homonuclear dipolar interaction scales as

$$\hat{\mathcal{H}}_{\text{DII}} \propto \hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2 - 3\hat{I}_{z1}\hat{I}_{z2} \quad (25)$$

A sequence that averages both of these interactions to zero at cycle time 3τ is $(\tau, 90_x, \tau, 90_y, \tau)$. The mechanics may be worked out by the reader, or one can refer to **CRAMPS** for an example of how this works. We must remind ourselves here that the condition for the production of an echo is that the initial signal be ‘sharp’ enough, and the reflecting wall ‘hard’ enough. This translates to the physical fact already alluded to that the magnitude of $\hat{\mathcal{H}}_{\text{rf}}$ must be larger than the magnitudes of the internal Hamiltonians being attacked by the rf. While this can be made generally true for dipolar interactions, it is not generally so for quadrupolar interactions, where in general the magnitude of $\hat{\mathcal{H}}_{\text{rf}}$ will be of the order of or smaller than $\hat{\mathcal{H}}_Q$. A case where the rf field is sufficiently larger than the quadrupolar interaction is that of aluminum metal, and Mehring has used this sequence to average the first-order quadrupolar interaction in this system to zero (see page 80 of Mehring⁸). These sequences are further discussed in **CRAMPS**.

8 TRANSIENT NUTATIONS: A VARIANT

An interesting variant of an echo in a solid, meaning an internal Hamiltonian has been averaged to zero at the echo time, is that of the transient nutation¹² experiment, in which the spins of an ensemble of dipolar coupled spin- $\frac{1}{2}$ nuclei are ‘nutated’ (spun around) the x axis in the rotating frame by a strong rf field in the x phase. The field is turned off at intervals, and the magnetization along the y axis sampled, in a closely analogous way to a multiple pulse experiment, where the magnetization is sampled in the windows of the experiment where some internal Hamiltonian is averaged to zero. In this case, the dipolar Hamiltonian may be written as

$$\begin{aligned} \hat{\mathcal{H}}_{\text{D}}/\omega &\equiv \hat{\mathcal{H}}_{zz} = \hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2 - 3\hat{I}_{z1}\hat{I}_{z2} \\ &\equiv -\frac{1}{2}(\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2 - 3\hat{I}_{x1}\hat{I}_{x2}) \\ &\quad + \frac{3}{2}(\hat{I}_{y1}\hat{I}_{y2} + 3\hat{I}_{z1}\hat{I}_{z2}) \\ &\equiv -\frac{1}{2}\hat{\mathcal{H}}_{xx} + \frac{3}{2}(\hat{I}_{y1}\hat{I}_{y2} + 3\hat{I}_{z1}\hat{I}_{z2}) \end{aligned} \quad (26)$$

The terms in $\hat{\mathcal{H}}_{xx}$, commuting with $\hat{I}_x$, the dominant interaction from the rf in the rotating frame, are secular. The other terms are nonsecular, do not commute with the major Hamiltonian, and therefore oscillate themselves out of sight. Under this sequence, therefore, the dipolar Hamiltonian is scaled by a factor of $\frac{1}{2}$, the chemical shift is averaged to zero, and for systems in which the shielding anisotropy is of order of magnitude of the dipolar interaction, e.g., ^{13}C – ^{13}C pairs in which both shielding anisotropy and homonuclear dipolar coupling are about 3 kHz at fields of roughly 2.3 T, the dipolar coupling can be clearly dug out from under the combined dipolar shielding signal.

9 MULTIPLE QUANTUM COHERENCE

Further, with a bit of imagination, one can see that it might not be desirable to average a given interaction to zero, but to manipulate it in order to obtain information hitherto not available, e.g., counting of the number of spins in a small cluster. This subject is discussed in ***Multiple Quantum Coherence Imaging, Multiple Quantum Coherence in Spin-1/2 Dipolar Coupled Solids*** and ***Multiple Quantum Coherences in Extended Dipolar Coupled Spin Networks***

1 INTRODUCTION

The literature on electron–nuclear hyperfine coupling as measured by NMR is so large that a comprehensive survey would by far exceed the scope of this article. Hence we concentrate on the principles which determine the applicability and the limitations of this method. The selection of the few examples given is necessarily subjective; for reasons discussed below, we have restricted ourselves to free radicals in solution.

The electron–nuclear hyperfine interaction between a nuclear spin and an unpaired electronic spin causes a splitting of the resonance absorption lines of electron paramagnetic resonance (EPR) which is termed ‘hyperfine splitting’ (HFS). The splitting is usually described in terms of a coupling constant a_i for the i th nucleus given either in tesla or in hertz; it was measured in the first 20 years of NMR by analyzing the splitting in the EPR spectrum. While the obtainable resolution of NMR depends mainly on the homogeneity of the external magnetic field B_0 , the resolution of EPR depends on the relaxation phenomena of the unpaired electrons which contribute to the transverse relaxation time T_2 of the electronic spin and hence to the linewidth. It would be outside the scope of this paper to discuss the various mechanisms which contribute to the linewidth—in particular the spin–orbit interaction can broaden the line in metal complexes beyond the resolvability of HFS. It turns out that free radicals in solution are the most suitable systems for studying hyperfine interactions.

The HFS can frequently not be resolved, even in solutions of free radicals consisting of first row elements in low viscosity liquids where the spin–orbit interaction and dipolar broadening are negligible. This is often due to the interaction of the unpaired spins of the electrons with the paramagnetic oxygen O_2 present in most solvents in contact with air. Therefore, the linewidth can be drastically decreased and the resolution correspondingly increased by carefully removing O_2 from the solvent.¹ This is illustrated by the example given in Figure 1, the EPR spectrum of 2,4,6-triphenylphenoxyl in benzene.²

However, even without oxygen the HFS in EPR spectra cannot be resolved in many cases. This is due to the large number of lines in an EPR spectrum because the total number of HFS components equals the product of the number of lines

Figure 1 EPR spectra of 2,4,6-triphenylphenoxyl in benzene (concentration $5 \times 10^{-4} \text{ mol l}^{-1}$): (a) saturated with air, (b) after the exclusion of oxygen

originating from nonequivalent nuclei (nuclei with identical HFS coupling constants are termed ‘equivalent’). If a free radical contains three types of equivalent protons, namely l_i protons with coupling constant a_i , m_j with coupling constant a_j , and n_k with coupling constant a_k , the total number of HFS lines is $(l + 1)(m + 1)(n + 1)$, which easily leads to several hundreds and even thousands of HFS components. If this large number of HFS lines cannot be resolved, the coupling constants can be measured in many cases by means of electron–nuclear double resonance (ENDOR) or electron–nuclear triple resonance.^{3–5} For the example given above, one expects six ENDOR absorption lines, two for each type of equivalent protons. One drawback of ENDOR is that the number of equivalent nuclei that cause an ENDOR transition can usually not be deduced from an ENDOR spectrum, since the intensity of the lines is not proportional to the number of equivalent nuclei, but depends in a complicated manner on the relaxation processes within the sample; we shall not discuss this further here since it is not the topic of this paper, but it is dealt with in another article in this Encyclopedia (see *Electron–Nuclear Multiple Resonance Spectroscopy*).

Although ENDOR may help by very drastically reducing the number of absorption lines in cases where the coupling constants cannot be measured by high-resolution ESR because the number of HFS components is too high, both methods fail in the case of small coupling constants.

2 PRINCIPLE

The interaction of a nucleus with spin $I = \frac{1}{2}$ and a magnetogyric ratio γ_I and an unpaired electron with spin $S = \frac{1}{2}$ and a magnetogyric ratio γ_S in an external magnetic field B_0 can be described by the Hamiltonian

$$\hat{\mathcal{H}} = \gamma_S \hbar (\hat{S} \cdot B_0) + \gamma_I \hbar (\hat{I} \cdot B_0) + \gamma_S \gamma_I \hbar^2 \times \left[\frac{8}{3} \pi |\Psi_{(0)}|^2 (\hat{I} \cdot \hat{S}) + \frac{3(\hat{I} \cdot r)(\hat{S} \cdot r)}{r^5} - \frac{(\hat{I} \cdot \hat{S})}{r^3} \right] \quad (1)$$

The first two terms are the electronic and nuclear Zeeman term; the third term is the scalar Fermi contact term which causes the hyperfine splitting.

Figure 2 Energy levels and transitions in a coupled two-spin system of one electronic spin $S = \frac{1}{2}$ and one nuclear spin $I = \frac{1}{2}$

The fourth term, (the dipolar term) depends explicitly on the angle Θ between the vector $\mathbf{r}$ connecting $\mathbf{S}$ and $\mathbf{I}$ and the magnetic field $\mathbf{B}_0$. The term is averaged out to zero by the molecular motion in low viscosity liquids and hence does not contribute to the time-independent interaction, i.e. the energy levels, but it must be taken into account for the time-dependent interactions, such as relaxation and dynamic nuclear polarization (DNP).

It is instructive to consider the energy levels and possible transitions given by the first three time-independent terms of this two-spin system (Figure 2) the method is easily extended to more nuclei as are present in most practical cases, but the simple example shown in Figure 2 is suitable for understanding the principle. On the left, we recognize the four energy levels originating from the secular parts (the z components) of the first and third terms in the Hamiltonian [equation (1)] and the corresponding EPR transitions. When considering ENDOR, the second term in equation (1), the nuclear Zeeman term, must be taken into account. This leads to the energy levels and the corresponding ENDOR transitions shown in the center of Figure 2.

In principle, the energy levels of the NMR shown on the right in Figure 2 should also be split into two lines with the same splitting constant a . However, this splitting cannot be observed because the NMR lines are broadened by at least two types of time-dependent phenomena associated with the unpaired electrons; first, electronic spin–lattice relaxation with the time constant $T_{1,S}$ and second, electronic exchange with the time constant τ_{ex} . In general, these time constants are sufficiently short to satisfy the following condition

$$T_{1,S} \ll \frac{1}{2\pi a} \quad \text{and/or} \quad \tau_{ex} \ll \frac{1}{2\pi a} \quad (2)$$

Hence one obtains in this case, instead of a splitting, a paramagnetic shift $\Delta B = B_d - B_p$ or $\Delta\nu = \nu_p - \nu_d$.^{6,7} In this

paper we use frequency units rather than magnetic field units since they give a direct measure of the energy differences and since the coupling constant a is identical whether it is measured by EPR or by NMR, while in magnetic field units the ratio of the magnetogyric ratios of the electron and the nucleus must be taken into account.

A paramagnetic shift δ_p termed the isotropic hyperfine contact interaction shift was defined⁶ in analogy to the diamagnetic chemical shift but with the opposite sign, i.e. with a positive sign for a downfield shift and a negative sign for an upfield shift. Since the magnitude of δ_p depends on the Boltzmann factor of the electronic Zeeman energy levels, it is temperature dependent. Its magnitude measured in ppm is given by

$$\delta_p(T) = \frac{B_d - B_p}{B_d} = \frac{a' \hbar \gamma_S^2}{4kT\gamma_I} \quad (3a)$$

$$\delta_p(T) = \frac{\nu_p - \nu_d}{\nu_d} = \frac{ah\gamma_S}{4kT\gamma_I} \quad (3b)$$

where the coupling constant a' is measured in tesla and a is in hertz. For protons at room temperature the result is

$$\delta_p(295 \text{ K}) = a \cdot 26.8 \text{ ppm MHz}^{-1} \quad (3c)$$

Note that with this definition the paramagnetic shift is not measured with respect to any standard, but is measured with respect to the same nucleus in a diamagnetic molecule as similar as possible to the radical.

As $\delta_p(T)$ is proportional to the coupling constant a , the latter can be determined by measuring $\delta_p(T)$ using NMR as well as from the HFS of EPR. At room temperature the coupling constant a_i of the i th nucleus is given by

$$a_i = \frac{4kT\gamma_I}{h\gamma_S} \delta_p(295 \text{ K}) \text{ MHz} \quad (4a)$$

Inserting the constants, one obtains for protons

$$a_i = 3.73 \times 10^{-2} \delta_p(295 \text{ K}) \text{ MHz} \quad (4b)$$

Measuring the coupling constant a by NMR has one additional advantage: while EPR renders only the absolute value of a , $\delta_p(T)$ gives the sign as well. This is particularly valuable for small coupling constants. While in the case of medium or large coupling constants the sign can usually be calculated theoretically with high certainty, this is not so for small coupling constants, the measurement of which is the main domain of NMR.

3 ¹H NMR

The first NMR spectrum of a free radical, namely di-*t*-butyl nitroxide (DBNO), which is a liquid at room temperature, is shown (with TMS as an internal standard) in Figure 3.⁶ The linewidth is found to be $\Delta\nu = 230 \text{ Hz}$ and the shift $\delta_p(295 \text{ K}) = -8.0 \text{ ppm}$ which, following equation (4), give a coupling constant $a_i = -0.298 \text{ MHz}$. Note that in this case $\delta_p(T)$ was

Figure 3 ^1H NMR spectrum of the liquid free radical di-*t*-butyl nitroxide with TMS as internal standard

measured with respect to the internal standard TMS because no diamagnetic molecule of similar structure was available; since the ^1H nuclei in TMS are also in methyl groups, the deviation can be assumed to be rather small. It has been pointed out⁸ that to obtain the correct paramagnetic shift $\delta_p(T)$ for neutral radicals its dependence on the concentration of the paramagnetic species must be measured and extrapolated to zero, because otherwise the varying magnetic susceptibility falsifies the result. This is certainly true when using an external standard. However, when using an internal standard, either a general standard like TMS for ^1H nuclei or an atom in a molecule that is as similar as possible, this effect is compensated for by the fact that the standard is in a medium with the same bulk susceptibility as the radical. In this case, the error when measuring the different concentrations up to a neat liquid radical stays usually below 10%, i.e. it does not exceed the typical solvent effect.

It is obvious that the critical quantity in NMR measurements of paramagnetic species is the linewidth, since this determines both the possible resolution and the sensitivity. For nuclei with spin $I = \frac{1}{2}$ in paramagnetic compounds the linewidth $\Delta\nu$ is proportional to the square of the interaction between the nucleus and the unpaired electron. The two main types of interaction are the scalar contact interaction discussed above and the dipolar interaction. For larger coupling constants a_i , the scalar interaction dominates, but for small a_i values the two can become comparable.

Since the linewidth $\Delta\nu \propto a_i^2$, medium and large values of a_i lead in general to very broad, unobservable NMR absorption lines. However, this broadening effect can be averaged out by sufficiently short time constants. The condition for obtaining narrow lines is much more limiting than equation (2), namely

$$T_{1,S} \ll \frac{1}{2\pi\nu_S} \quad (5)$$

$$\tau_{\text{ex}} \ll \frac{1}{2\pi\nu_S} \quad (6)$$

where ν_S is the Larmor frequency of the electron. Equation (5) and/or equation (6) may be satisfied in favorable cases of certain metal chelate compounds for which very narrow lines have been obtained.

Several attempts can be made to reduce the linewidth to come closer to the condition given in equation (6).

Figure 4 ^1H NMR spectrum of 3,6-dimethyl-1,5-diphenylverdazyl in DBNO

One possibility is to use the liquid free radical DBNO as solvent.⁹ Figure 4 shows as an example the NMR spectrum of 3,6-dimethyl-1,5-diphenylverdazyl in DBNO at a resonance frequency of 90 MHz.⁷ The linewidth varies from about 0.09 MHz to 0.3 MHz, and the different NMR absorption lines are well resolved. The paramagnetic shifts $\delta_p(295\text{ K})$ with respect to the corresponding ^1H resonances of the diamagnetic leucoverdazyl vary between -148 and $+63.5$ ppm. As expected, the linewidth increases with the coupling constant, but even the absorption line of the ^1H atoms in the methyl group in the R^3 position in the central ring, with a linewidth of about 250 kHz, is easily seen although it has a coupling constant as large as $a_i = -5.52$ MHz. One problem with DBNO is that some absorption lines may be hidden below the broad absorption line of DBNO, in this example the line due to the H atom at the C atom in the central ring. In general, the gain in resolution when using DBNO as a solvent is one order of magnitude for larger coupling constants, but much lower for absorption lines of nuclei with small coupling constants.

4 NMR WITH OTHER NUCLEI

Another approach to increasing the resolution is to use ^2H NMR instead of ^1H NMR. The paramagnetic shift of the deuterons (in ppm) is, of course, identical to the shift of the protons. Because of the much smaller magnetogyric ratio of the deuterons one expects a reduction of the shift measured in hertz by a factor of γ_P/γ_D , but a reduction of the linewidth by the square of this quantity $(\gamma_P/\gamma_D)^2$. Hence the net increase in resolution when using deuterons instead of protons should be proportional to $\gamma_P/\gamma_D \approx 6.5$.

The ^2H NMR spectrum of 3-*t*-butyl-1,5-bis(pentadeutero-phenyl)verdazyl in DBNO is reproduced as an example in Figure 5.⁷ The gain in resolution when using ^2H NMR instead of ^1H NMR is found to be about a factor of 2 to 3, but not 6 as expected from theory, considering the Fermi contact interaction only. It follows that the best possible resolution can be obtained using ^2H NMR in DBNO; the maximum gain in resolution $\Delta\nu/\nu$ which is obtained in practice is a factor of about 20.

Figure 5 ^2H NMR spectrum of 3-*t*-butyl-1,5-bis(pentadeuterophenyl)verdazyl in DBNO

The measurement of the coupling constant a_i was extended to ^{13}C NMR.¹⁰ In cases where a_i could be measured by ESR as well, good agreement was found in general. Differences are of the same order (about 10%) as found with ESR in different solvents; the concentration dependence mentioned above also plays a role, since the NMR is usually measured at high concentration ($>2\text{ M}$), while the concentration with the ESR measurements was mostly about 10^{-3} – 10^{-4} M .¹¹ While the coupling constant a_i of the ^1H nucleus is generally mainly determined by the spin density at the atom to which the ^1H is bound (with some geometrical effects), ^{13}C NMR measurements of a series of nitroxide radicals showed that the coupling constants a_i depend in a more complex manner on the polarization of the electrons in the nitrogen–carbon bond and on the carbon–carbon bonds, as well as on geometrical effects.¹¹ The situation is even more complicated with aromatic fluoro compounds where the spin polarization between the 2p orbital of the fluorine and the spin in the 2p orbital of the adjacent carbon atom has to be considered. In favorable cases the sign and magnitude of the fluorine coupling could be obtained.¹²

5 NMR OF RADICAL IONS

A somewhat different situation is encountered when measuring the NMR of radical ions in solution. In general, in the solution both neutral molecules M and the corresponding negative radical ions M^- will be present. In this case there is an electron transfer reaction between these two species, which may be symbolized by¹³

Here the paramagnetic shift $\delta_p(T)$ of a nucleus in the molecule is not given directly by equation (3), but the fraction f_p

of paramagnetic radicals in the solution must be taken into account; this is given by

$$f_p = \text{M}^- / (\text{M} + \text{M}^-) \quad (8)$$

Hence the paramagnetic shift $\delta'_p(T)$ becomes

$$\delta'_p(T) = f_p \delta_p(T) \quad (9)$$

Since the measured quantity in this case is $\delta'_p(T)$, in equation (4), $\delta_p(T)$ must be replaced by $\delta_p(T)/f_p$ in order to obtain the coupling constant a_i . The fraction f_p can be determined from the solvent shift due to the change in the susceptibility of the solution as a function of the reduction of the molecule M .¹³

It was stated above that measurement of the coupling constant a_i of a nucleus within a neutral free radical by NMR is usually restricted to small coupling constants. However, in the case of radical ions the chemical exchange with the time constant $\tau_{\text{ex}}^{\text{ch}}$ can be so fast that it approaches the much stricter conditions of equations (5) and (6); it was estimated to be of the order of $\tau_{\text{ex}}^{\text{ch}} \simeq 10^{-11}$.¹⁴ This is illustrated by the example of biphenyl in diglyme.

Figure 6 shows the ^1H NMR spectrum of biphenyl in diglyme. The ^1H NMR line of the *meta* protons is much sharper and shifted downfield, as would be expected from the negative spin density at the *meta* carbon atom in biphenyl, as opposed to the much broader lines of the *ortho*- and *para*- ^1H atoms. The paramagnetic shift $\delta_p(T)$ of the *ortho*- and *meta*- ^1H atoms is plotted in Figure 7¹⁴ as a function of the solvent shift $\delta_s(T)$ in diglyme when the biphenyl is gradually reduced with sodium.

Over the past 20 years the coupling constants between ^1H and ^2H nuclei and the unpaired electron spins have been measured in many such chemical exchange systems. In the case of ion radicals, even the coupling between the negative ion radicals and the alkali metal counterions (^6Li , ^{23}Na , ^{39}K , etc.) could be measured from the NMR of the alkali metals and the solvent, temperature and concentration dependence could be studied.¹⁵ For more information on hyperfine interaction in NMR, the reader is referred to a series of review articles on the subject which cover the period from 1972 until 1990.¹⁶

Figure 6 ^1H NMR spectrum at room temperature of a completely reduced 1 M solution of biphenyl in diglyme, with sodium as the reducing agent. S, solvent peak. All the peaks were measured with different rf power, gain, and modulation

Figure 7 Contact shift δ_c at room temperature of *ortho*- ^1H and *meta*- ^1H of biphenyl as a function of the solvent shift δ_s for a solution of diglyme (concentration 1 M) gradually reduced with sodium

1 INTRODUCTION

NMR has proven to be of great utility in the study of paramagnetic proteins. Although the presence of the paramagnetic center creates inherent difficulties in obtaining structural information from nearby residues, numerous solution structures now exist for certain classes of paramagnetic proteins.^{1–3} In addition, the interactions between the unpaired electron and surrounding nuclei create new effects that provide sensitive probes of the electronic and geometric structure of the paramagnetic center. Traditionally, it has been very difficult to obtain quantitative information from these electron–nuclear interactions, but with the advent of reliable, high-level computational techniques and the development of new NMR methodologies, this has begun to change. In coupled systems, a vector coupling model has been of great utility in providing a qualitative picture. In this review, we focus exclusively on FeS proteins, which have been extensively studied by NMR, and although they pose some of the greatest challenges, they have yielded some of the most satisfying agreement between theory and experiment.

2 ELECTRON–NUCLEAR INTERACTIONS IN MONONUCLEAR SYSTEMS

Paramagnetic proteins containing a single transition metal site represent the simplest case for the study of electron–nuclear interactions. Even in these systems, however, the analysis of the resulting effects can be quite complex.

2.1 Theory

We discuss here three types of electron–nuclear interactions: hyperfine shifts,^{4,5} paramagnetic relaxation,^{4–6} and residual dipolar couplings.^{7,8} Electron–nuclear interactions provide an additional contribution to the chemical shift, called

the hyperfine shift. This frequently results in peaks appearing far outside the region typical for diamagnetic shifts. Electron–nuclear interactions also give rise to additional NMR relaxation mechanisms that can broaden peaks and make them inaccessible to detection by traditional multidimensional NMR approaches. Residual dipolar couplings appear when a molecule becomes partially ordered with respect to the external magnetic field of the NMR experiment. A protein with an anisotropic magnetic susceptibility tensor will become ordered in a strong magnetic field; and this ordering will show up as changes in couplings between the nuclei of nearby magnetically active atoms. All three effects, hyperfine shifts, paramagnetic relaxation, and residual dipolar couplings, can be rich sources of information about protein structure and the properties of the metal site.

Hyperfine shifts arise from the sum of two distinct interactions: the Fermi contact shift, δ_{con} , and the electron–nuclear dipolar or pseudocontact shift, δ_{pc} . The observed chemical shift, δ_{tot} , is the sum of these two plus the diamagnetic chemical shift, δ_{dia} :

$$\delta_{\text{tot}} = \delta_{\text{con}} + \delta_{\text{pc}} + \delta_{\text{dia}} \quad (1)$$

The Fermi contact shift arises from delocalization of unpaired electron density onto ligand orbitals. Only unpaired spin density at the nucleus contributes to the Fermi contact coupling. The equation for the Fermi contact shift in ppm is:

$$\delta_{\text{con}} = 10^6 \left(\frac{\Delta\nu}{\nu_0} \right)^{\text{con}} = -10^6 \frac{A}{\hbar\gamma_N B_0} \langle S_z \rangle \quad (2)$$

where A is the isotropic hyperfine constant in Joules and $\langle S_z \rangle$ is the expectation value of S_z . (Note that hyperfine coupling is usually reported as $A/\hbar$, which has units of hertz.) In the absence of first-order orbital angular momentum or zero-field splitting (ZFS), this simplifies to:

$$\delta_{\text{con}} = 10^6 \left(\frac{\Delta\nu}{\nu_0} \right)^{\text{con}} = 10^6 \left(\frac{A}{\hbar} \right) \frac{g\mu_B S(S+1)}{3\gamma_N kT} \quad (3)$$

where g is the average molecular electron g -value (frequently assumed to be $\sim g_e$, the free electron g -value). This isotropic hyperfine coupling constant can in turn be related to the unpaired spin density at the nucleus:

$$A = \frac{\mu_0}{3S} \hbar\gamma_N g\mu_B \sum_i [|\psi_i^-(0)|^2 - |\psi_i^+(0)|^2] \quad (4)$$

where $|\psi_i^-(0)|^2$ and $|\psi_i^+(0)|^2$ are the negative and positive spin density at the nucleus of the i th molecular orbital.

The pseudocontact shift is the other contribution to the hyperfine shift. The electron magnetic moment is anisotropic as a result of coupling with the orbital angular momentum, and thus it does not average to zero with molecular tumbling. This yields an isotropic shift that is dependent upon the electron–nuclear distance. The ‘point-dipole’ approximation is usually invoked, in which all of the unpaired electron density is localized at the metal center. This yields:

$$\begin{aligned} \delta_{\text{pc}} &= 10^6 \left(\frac{\Delta\nu}{\nu_0} \right)^{\text{pc}} = 10^6 \frac{1}{8\pi r^3} \left[(3\cos^2\theta - 1) \right. \\ &\quad \times \left(\frac{2}{3}\chi_{zz} - \frac{1}{3}\chi_{xx} - \frac{1}{3}\chi_{yy} \right) \\ &\quad \left. + \sin^2\theta \cos 2\phi (\chi_{xx} - \chi_{yy}) \right] \end{aligned} \quad (5)$$

where r is the electron–nuclear distance, χ_{zz} , χ_{xx} , and χ_{yy} are the principle components of the magnetic susceptibility tensor, and θ and ϕ are the angles formed by r and the molecular z axis and the projection of r in the xy plane with the molecular x axis. Again, assuming no ZFS, this simplifies to:

$$\begin{aligned} \delta_{pc} = 10^6 \left(\frac{\Delta\nu}{\nu_0} \right)^{pc} = 10^6 \frac{\mu_0 \mu_B^2 S(S+1)}{4\pi 18kTr^3} \\ \times [2g_{zz}^2 - (g_{xx}^2 + g_{yy}^2)](3\cos^2\theta - 1) \\ + 3(g_{xx}^2 - g_{yy}^2)\sin^2\theta\cos 2\phi \end{aligned} \quad (6)$$

In analyzing hyperfine shifts, a first step is the separation of the Fermi contact and pseudocontact contributions. As seen in equation (5), the pseudocontact shift is related to the magnetic susceptibility anisotropy. In FeS systems at room temperature, this is small, and for nuclei that are only a few bonds away from the Fe, the Fermi contact term will overwhelmingly dominate. For nuclei close in space but many bonds away from the Fe, the pseudocontact shift will dominate, and can in principle provide useful distance information.

As in the case of hyperfine shifts, the paramagnetic contribution to the nuclear T_1 and T_2 relaxation rates arise from several different contributions: electron–nuclear dipolar, contact, and Curie spin. The equations for these are

$$\begin{aligned} T_{1dip}^{-1} = \frac{2}{15} \left(\frac{\mu_0}{4\pi} \right)^2 \frac{\gamma_N^2 g^2 \mu_B^2 S(S+1)}{r^6} \\ \times \left[\frac{\tau_c}{1 + (\omega_I - \omega_S)^2 \tau_c^2} + \frac{3\tau_c}{1 + \omega_I^2 \tau_c^2} \right. \\ \left. + \frac{6\tau_c}{1 + (\omega_I + \omega_S)^2 \tau_c^2} \right] \end{aligned} \quad (7)$$

$$T_{1con}^{-1} = \frac{2}{3} \left(\frac{A}{h} \right)^2 S(S+1) \frac{\tau_e}{1 + (\omega_I - \omega_S)^2 \tau_e^2} \quad (8)$$

$$\begin{aligned} T_{2dip}^{-1} = \frac{1}{15} \left(\frac{\mu_0}{4\pi} \right)^2 \frac{\gamma_N^2 g^2 \mu_B^2 S(S+1)}{r^6} \\ \times \left[4\tau_c + \frac{\tau_c}{1 + (\omega_I - \omega_S)^2 \tau_c^2} + \frac{3\tau_c}{1 + \omega_I^2 \tau_c^2} \right. \\ \left. + \frac{6\tau_c}{1 + (\omega_I + \omega_S)^2 \tau_c^2} + \frac{6\tau_c}{1 + \omega_S^2 \tau_c^2} \right] \end{aligned} \quad (9)$$

$$T_{2con}^{-1} = \frac{1}{3} \left(\frac{A}{h} \right)^2 S(S+1) \left[\tau_e + \frac{\tau_e}{1 + (\omega_I - \omega_S)^2 \tau_e^2} \right] \quad (10)$$

$$T_{2curie}^{-1} = \frac{1}{5} \left(\frac{\mu_0}{4\pi} \right)^2 \frac{\omega_I^2 g^4 \mu_B^4 S^2(S+1)^2}{(3kT)^2 r^6} \left[4\tau_r + \frac{3\tau_r}{1 + \omega_I \tau_r^2} \right] \quad (11)$$

where ω_I and ω_S are the nuclear and electron Larmor precession frequencies, τ_r is the rotational correlation time, τ_e is the electronic relaxation rate, and τ_c is the total correlation time, given as:

$$\tau_c^{-1} = \tau_r^{-1} + \tau_e^{-1} \quad (12)$$

In these equations, several simplifying assumptions have again been made: the point-dipole approximation holds, g is isotropic, and ZFS is negligible. More complex equations have

been derived that include g anisotropy and ZFS.⁶ Of these simplifications, the point-dipole approximation generally is the one that fails in a quantitative analysis of relaxation rates. This is especially the case in Fe–S proteins, where the Fe is highly covalent and the electron density is delocalized significantly out onto the ligands. This is sometimes referred to as the ‘ligand-centered’ dipolar contribution to the relaxation rate, and attempts have been made to account for it.⁹ In the high-temperature limit, the electronic transverse and longitudinal relaxation rates (T_{1e} , T_{2e}) are essentially equal, and this can be taken as the value of τ_e . The contributions to τ_e are numerous, and in general, prevent its independent determination. Nonetheless, τ_e is assumed to be $\sim 10^{-10}$ – 10^{-11} s for mononuclear high-spin (h.s.) Fe^{3+} and $\sim 10^{-11}$ – 10^{-12} s for mononuclear h.s. Fe^{2+} .⁶ Curie spin relaxation, which arises from the interaction of the nuclear magnetic moment with the large static magnetic moment provided by the unpaired electrons of the metal center, can be by far the dominant contribution to T_2 , especially at high fields, for proteins with a high-spin metal site (e.g., h.s. Fe^{3+}) and/or high molecular weight. The Curie spin contribution to T_1 is very small and can be ignored. Because of the strong dependence of the relaxation rate on the nuclear magnetogyric ratio, γ , hyperfine signals from nuclei with a low γ (e.g., ^{15}N and 2H) are more readily observed than signals from nuclei with high γ (1H). Thus, one strategy for the study of paramagnetic systems is to collect 1D ^{15}N and 2H NMR data on isotopically labeled samples. Note that the chemical shifts of 1H and 2H are essentially equivalent.

The third type of electron–nuclear interaction is residual dipolar coupling. In solution-state NMR, rapid molecular tumbling normally averages out dipolar couplings. However, in a system with a sufficiently anisotropic magnetic susceptibility tensor, a high magnetic field can lead to partial ordering of the molecules. Because the effect is proportional to the square of the magnetic field, the dipolar couplings can be extracted from analysis of one-bond 1H – X couplings at two different fields. The magnitude of $^1D_{HX}$ is related to the magnetic susceptibility anisotropy:

$$\begin{aligned} ^1D_{HX} = \frac{-\gamma_X \gamma_H B_o^2}{40kT\pi^2 r^3} \left[(3\cos^2\theta - 1) \left(\chi_{zz} - \frac{1}{2}\chi_{xx} - \frac{1}{2}\chi_{yy} \right) \right. \\ \left. + \frac{3}{2}\sin^2\theta\cos 2\phi(\chi_{xx} - \chi_{yy}) \right] \end{aligned} \quad (13)$$

Note that the form of this equation is very similar to that for the pseudocontact shift (equation 5); however, residual dipolar couplings can be measured directly, whereas pseudocontact shifts must be deconvoluted from the Fermi contact and diamagnetic components of the observed chemical shift.

2.2 Applications to Fe(Cys)₄ Proteins

The most extensive study of hyperfine shifts in Fe(Cys)₄ proteins is for *Clostridium pasteurianum* rubredoxin (CpRd). Extensive and definitive assignments were obtained for the H and N atoms of the ligating Cys residues and eight nearby amide N atoms in both oxidation states through the use of selective 2H and ^{15}N labeling, including chirally deuterated Cys and single-site labeling (Figure 1(a)–(f), Table 1).^{10–13} Also, the Cys C $^\beta$ resonances from reduced CpRd were identified by selective labeling (Figure 1(g), Table 1).¹²

For CpRd, Fermi contact shifts were calculated with hybrid density functional theory (HDFT) using 104-atom models¹⁴ derived from three published crystal structures of oxidized CpRd at 1.1–1.2 Å resolution.^{15–17} Extremely good agreement was obtained between the calculated Fermi contact shifts and all of the observed ^2H and ^{15}N hyperfine shifts for all three models (in one model, a correction to the placement of the amide H atoms was required). The pseudocontact shift was small enough that it could safely be ignored. The agreement between calculated and experimental hyperfine shifts was excellent. All assignments achieved by selective labeling were confirmed in the calculations, and the calculations allowed definitive sequence-specific assignments for nearly all the remaining hyperfine-shifted ^2H and ^{15}N signals. These results validate the approach and indicate that HDFT calculations are a powerful tool for obtaining a quantitative understanding of hyperfine shifts and electronic structure of metalloproteins.

In the case of CpRd, this approach demonstrated the importance of hydrogen bonding to the ligating Cys S^γ atoms. In CpRd, six backbone amides donate H-bonds to the Cys S^γ atoms: residues Val8, Cys9, Tyr11, Leu41, Cys42, and Val44. In particular, the N atoms of Tyr11 and Val44 exhibit large hyperfine shifts but are eight covalent bonds from the

Fe. The conclusion, corroborated by the HDFT calculations, is that H-bonds are capable of delocalizing spin density, a feature that may be important in the electron transfer function of these systems. The calculations further showed an inverse correlation between the magnitude of the hyperfine shift and $\text{H}\cdots\text{S}^\gamma$ distance. (Signals from the ^{15}N atoms of the ligating Cys residues have a separate intercept because they also derive appreciable unpaired spin density through covalent bonds.) Another effect of spin delocalization through H-bonds is the large (≥ 8 ppm) negative one-bond $^1\text{H}/^2\text{H}$ isotope effects on the chemical shifts of the Val8, Tyr11, Leu41, and Val44 N atoms (Table 1).¹³ Again, HDFT calculations were able to quantitatively account for this isotope effect.¹³ Recent ^{15}N NMR data¹⁸ on a mutant of CpRd with a very different N– S^γ length for one of the H-bonds as determined by X-ray crystallography¹⁹ are consistent with the correlation between H-bond length, spin density, and in turn, hyperfine shift. The calculations also helped interpret the ^2H , ^{15}N , and ^{13}C chemical shifts for reduced CpRb.¹⁴ Since only coordinates for oxidized CpRd were available, the correlation between the experimental and calculated chemical shifts were not as good, and therefore the residue-specific assignments are only preliminary. Subsequent calculations based on the recently

^aChemical shifts in parentheses are for CpRd in D₂O; four resonances shift to higher frequency owing to a one-bond ¹H/²H isotope effect (see text for details).

published X-ray structure for reduced CpRd²⁰ are yielding improved agreement with experiment and hence more insight into the electronic structure.²¹

HDFT calculations were extended to obtain a quantitative understanding of the ¹⁵N *T*₁ relaxation rates in oxidized CpRd.²² In this system, the contact contribution is small even for the most strongly hyperfine-shifted resonances and the *T*₁ rates are dominated by electron–nuclear dipolar relaxation. However, given that the unpaired spin density in this system is known to be highly delocalized, the point-dipole approximation is a poor model. This was accounted for by replacing the *r*^{−6} distance dependence in equation (7) with an effective reciprocal distance, *r*_{eff}^{−6}:

$$r_{\text{eff}}^{-6} = \frac{1}{4} \left[\frac{1}{3} (\langle q_{xx} \rangle_{\text{spin}} - \langle q_{yy} \rangle_{\text{spin}})^2 + \langle q_{xx} \rangle_{\text{spin}}^2 + \frac{4}{3} (\langle q_{xy} \rangle_{\text{spin}}^2 + \langle q_{xz} \rangle_{\text{spin}}^2 + \langle q_{yz} \rangle_{\text{spin}}^2) \right] \quad (14)$$

In equation (14), the $\langle q_{\alpha\beta} \rangle_{\text{spin}}$ terms are the matrix elements of the spin-differential field gradient tensor:

$$\langle q_{\alpha\beta} \rangle_{\text{spin}} = \sum_{st} D_{st} \langle s | \hat{q} | t \rangle \quad (15)$$

where *D*_{st} is the normalized, spin-only density matrix and *q*_{αβ} is the electric field gradient operator:

$$\hat{q}_{\alpha\beta} = \frac{3r_{\alpha}r_{\beta} - \delta_{\alpha\beta}r^2}{r^5} \quad (16)$$

This approach provided excellent agreement between experimental and calculated ¹⁵N *T*₁ rates, whereas the point-dipole model failed for nuclei closer than 7 Å. A comparison of *r*_{eff} with the crystallographic distance demonstrates this (Figure 2). These calculations yielded a *τ*_c of $\sim 4 \times 10^{-10}$ s. In this system, *τ*_c $\approx$ *τ*_e, and this value for *τ*_e is typical for Fe³⁺.

The magnetic field-dependence of one-bond ¹H–¹⁵N and ¹H^α–¹³C^α couplings were measured in order to determine the residual dipolar couplings in oxidized and reduced CpRd.⁸ These, in combination with the crystallographic data, were used to obtain the magnitude and orientation of the magnetic susceptibility anisotropy, Δ*χ*_{ax} and Δ*χ*_{rh} (Figure 3). By subtracting the calculated diamagnetic contribution from the protein, Δ*χ*_{ax} and Δ*χ*_{rh} for the metal center can be determined: 7.93×10^{-28} and 3.24×10^{-28} cm³ molecule^{−1} for oxidized and 22.3×10^{-28} and 10.5×10^{-28} cm³ molecule^{−1} for reduced CpRd, respectively (Table 2).

These values, in turn, can be compared with ZFS parameters and *g*-values previously obtained by other methods for rubredoxins and Fe(SR)₄ model complexes. Since the magnetic susceptibility anisotropies were measured at 10 °C, the values are very sensitive to small differences in both the **D**-

Figure 2 Plot of *r*_{xtal} − *r*_{eff} versus *r*_{xtal}, where *r*_{xtal} is the measured distance between individual ¹⁵N nuclei and the Fe atom in the 4RXN crystal structure and where *r*_{eff} is the effective distance calculated from the wave function using the spin-differential field gradient tensor method. Black circles represent ¹⁵N nuclei that give rise to hyperfine-shifted resonances and open circles represent the ‘diamagnetic’ ¹⁵N nuclei. The horizontal line is drawn at the zero of the abscissa. The inset plot shows an expansion of the ordinate for nuclei that are close to the metal center. Reproduced with permission from Ref.²² Copyright 1998 American Chemical Society

Figure 3 Structural representation of magnetic susceptibility anisotropies. A ribbon diagram of the structure of CpRd is shown, including the atoms of the $\text{Fe}(\text{Cys})_4$ center. Vectors originating at the Fe indicate the magnitudes and show the orientations of the $\Delta\chi_{\text{ax}}$ and $\Delta\chi_{\text{rh}}$ terms obtained from fits to the 5RXN structure of dipolar splittings from oxidized and reduced CpRd. The diamagnetic $\Delta\chi_{\text{ax}}$ and $\Delta\chi_{\text{rh}}$ values calculated for 5RXN are also shown. Reproduced with permission from Ref.⁸ Copyright 1998 American Chemical Society

and $\mathbf{g}$ -tensors and their relative orientation; thus, they can only be compared to the previous data in general terms.

ZFS parameters have been obtained for oxidized CpRd from Mössbauer spectroscopy^{23,24} and for oxidized *Pseudomonas oleovorans* rubredoxin from variable-temperature X-band EPR spectroscopy²⁵ (Table 2). Both approaches yielded a D that is small and positive, consistent with an approximately D_{2d} geometry; in these calculations, g was assumed to be isotropic and ~ 2.0 . The values of D , E , and g obtained from EPR can be used to calculate $\Delta\chi_{\text{ax}}$ and $\Delta\chi_{\text{rh}}$, which yields the qualitatively consistent values of 7.27×10^{-28} and $4.15 \times 10^{-28} \text{ cm}^3 \text{ molecule}^{-1}$, respectively. Agreement with the NMR-derived values can be improved substantially by assuming a g -anisotropy of 0.004; this small value is reasonable on the basis of data for a $\text{Fe}^{3+}(\text{SR})_4$ model complex.²⁶

ZFS parameters have been obtained for reduced CpRd from Mössbauer spectroscopy (Table 2)²³ and for a model complex, $[\text{Fe}(\text{SPh})_4]^{2-}$, from Mössbauer,²⁷ high-frequency EPR (HFEPR),²⁸ and far-infrared (FIR) absorption spectroscopies.²⁹ In the latter system, the ZFS parameters obtained from HFEPR and FIR were in agreement and significantly smaller than from those obtained from Mössbauer. Results from the model system were used to derive ZFS parameters for CpRd (Table 2).²⁸

In all cases, g -values were inferred from expressions derived from second-order perturbation theory (Table 2).³⁰ $\Delta\chi_{\text{ax}}$ and $\Delta\chi_{\text{rh}}$ values calculated from Mössbauer-derived values of D , E , and g are approximately twice the experimental values determined by NMR, whereas those derived from HFEPR (22.5×10^{-28} and $13.4 \times 10^{-28} \text{ cm}^3 \text{ molecule}^{-1}$, respectively) are in good agreement. Again, small changes in the g -anisotropy would account for the remaining difference.

Once the magnitude and orientation of the magnetic susceptibility anisotropy were determined for oxidized and reduced CpRd, these data could be used to estimate the pseudocontact shifts for nuclei $>11 \text{ Å}$ from the Fe center. From this it was found that pseudocontact shifts entirely accounted for the observed chemical shift differences between the oxidized and reduced states for the diamagnetic resonances. This, in turn, indicated that the structure of the protein 7 Å or more from the Fe remains the same in the two redox states.

3 EXCHANGE COUPLING AND ITS INFLUENCE ON ELECTRON–NUCLEAR INTERACTIONS

Electron–nuclear interactions in exchange coupled multinuclear systems are considerably more complicated than those in simple single-metal site systems. As with simpler systems, NMR data can be used to evaluate theoretical models describing the paramagnetic center. In particular, the nature of exchange coupling in the mixed-valence states of these clusters has been a topic of great interest. The types of exchange-coupled FeS clusters that have been studied by NMR spectroscopy and their different formal redox states are listed in Table 3. An extensive list of NMR results on different FeS proteins is provided in Table 4.

In this section, we present the theory of how exchange coupling impacts hyperfine shifts and paramagnetic relaxation. We then show how the vector coupling model of hyperfine shifts has been applied to representative FeS clusters and the insight this has provided.

3.1 Theory

In a coupled system, the exchange coupling can be described by the phenomenological spin Hamiltonian:

$$\mathcal{H} = \sum_{i < j} -2J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j \quad (17)$$

where J is the isotropic or Heisenberg exchange coupling constant and $\mathbf{S}_i$ and $\mathbf{S}_j$ are the local spin operators for each metal site. For a system with two metal centers, such as $[\text{2Fe–2S}]^{2+}$, this yields a set of levels or “spin ladder” for the total spin S , in which S ranges from $|\mathbf{S}_1 + \mathbf{S}_2|$ to $|\mathbf{S}_1 - \mathbf{S}_2|$, the relative energies of which are given by:

$$E(S) = -JS(S+1) \quad (18)$$

J can be positive (ferromagnetic coupling) or negative (antiferromagnetic coupling). In FeS clusters J is always negative. In mixed-valence systems, such as $[\text{2Fe–2S}]^+$, the extra electron can be on either Fe; this doubles the number of total spin states. Consideration of this effect, called double

Table 2 Comparison of the magnetic susceptibility anisotropy of oxidized and reduced rubredoxin obtained from NMR with the ZFS parameters and g -values obtained from Mössbauer and EPR and the magnetic susceptibility anisotropy calculated from these

		Oxidized rubredoxin	Reduced rubredoxin

exchange or spin-dependent delocalization, yields the following equation for the energies of the total spin states are now defined by:

$$E(S) = -JS(S+1) \pm B\left(S + \frac{1}{2}\right) \quad (19)$$

where B is the double exchange term. The interplay between J and B determines the ground state (g.s.) of the system. Two additional effects must be considered: static and dynamic asymmetry. Static asymmetry arises from differences in the coordination geometry, H-bonding, and protein electrostatics at the two Fe sites that cause the extra electron to be preferentially localized on one side. Dynamic asymmetry, or vibronic coupling, arises from the change in geometry upon transferring the extra electron from one side to the other. The magnitude of this nuclear distortion defines the height of the barrier to electron transfer between the two sides. Thus, in the limit of large B and small vibronic coupling, there is no barrier to intersite electron transfer and the system is said to be completely valence-delocalized. For example, a valence-delocalized [2Fe-2S]⁺ cluster would be described as 2Fe^{2.5+}. Together, static asymmetry and vibronic coupling counteract the effect of double exchange. In the limit where these effects are large relative to B , the system is valence-localized and can be described by equations (17) and (18),

where J is replaced by a J_{eff} , which is the Heisenberg J plus a correction factor to account for B , static asymmetry, and vibronic coupling. For systems of higher nuclearity, the exchange coupling can be described by decomposing the system into subunits and first considering the coupling within the subunits, and then the coupling between the subunits. For a more detailed account of exchange coupling, see Ref.³¹ and references therein.

In an exchange coupled system, the Fermi contact shift can still be described by equation (2), but now one must calculate the Fermi contact shift for each total spin state, each of which will have a different isotropic hyperfine coupling constant, A_i , and sum over the Boltzmann population of the total spin states. The difficulty lies in determining each A_i ; however, this can be accomplished readily because the hyperfine coupling constant for each total spin state S , in turn, can be related to the intrinsic hyperfine coupling constant for each metal site, A_j . Thus, equation (2) may be rewritten as:³²

$$\delta_{\text{con}} = 10^6 \left(\frac{\Delta\nu}{\nu_0} \right)^{\text{con}} = -10^6 \frac{1}{\hbar\gamma_N B_0} \sum_i \sum_j A_j C_{ji} \langle S_z \rangle_i \quad (20)$$

where C_{ji} are spin projection coefficients for each metal site j for each total spin state i . These are derived from the

Wigner–Eckart theorem and vector coupling.³³ For a binuclear system, C_1 is given by^{31–34}

$$C_1 = \frac{S(S+1) + S_1(S_1+1) - S_2(S_2+1)}{2S(S+1)} \quad (21)$$

where S is the total spin and S_1 and S_2 are the spin states of each metal site. C_2 is given by simply reversing the indices in equation (21). This can be easily extended to systems of higher nuclearity by use of a chain rule.³⁴ Consider a tetranuclear system that can be divided into two subunits of spin S_p and S_q . From equation (21), spin projection coefficients C_1^p and C_2^p can be calculated by replacing S with S_p and C_p by replacing S_1 and S_2 with S_p and S_q . Coefficients projecting out the spin onto the total spin state are then:

$$C_1 = C_1^p C_p \quad (22)$$

Note also that the spin projection coefficients for each total spin state always sum to one. Considering an explicit expression for the spin expectation value in equation (20) yields:

$$\begin{aligned} \delta_{\text{con}} &= 10^6 \left(\frac{\Delta\nu}{\nu_0} \right)^{\text{con}} = -10^6 \frac{g\beta}{\hbar\gamma_N 3kT} \\ &\times \sum_j \frac{A_j \sum_i C_{ji} S(S+1)(2S+1) \exp(-E_S/kT)}{\sum_i (2S+1) \exp(-E_S/kT)} \quad (23) \end{aligned}$$

Application of equation (23) is still difficult, and as shown below, has only been attempted qualitatively.

Paramagnetic relaxation can be analyzed by a treatment similar to equations (20) and (23). For example, the point-dipole approximation of the electron–nuclear dipolar contribution to T_1 may be written as:³²

$$\begin{aligned} T_{1j}^{-1} &= \frac{2}{15} \left(\frac{\mu_0}{4\pi} \right)^2 \frac{\gamma_N^2 g^2 \beta^2}{r_j^2} \frac{\sum_i C_{ji}^2 S(S+1)(2S+1) \exp(-E_S/kT)}{\sum_i (2S+1) \exp(-E_S/kT)} \\ &\times \left[\frac{\tau_c}{1 + (\omega_I - \omega_S)^2 \tau_c^2} + \frac{3\tau_c}{1 + \omega_I^2 \tau_c^2} + \frac{6\tau_c}{1 + (\omega_I + \omega_S)^2 \tau_c^2} \right] \quad (24) \end{aligned}$$

where T_{1j} is the dipolar relaxation from metal site j , r_j is the distance to that metal site, and τ_c is given as in equation (12). This is then summed over all metal sites. Similar equations may be derived for the other types of paramagnetic relaxation. The issue arises as to what value to use for the electronic relaxation rate. In the limit of strong exchange coupling, where the coupling frequency is large relative to the electronic relaxation rates for the uncoupled spins (τ_{ej}) but small relative to the electronic correlation time (τ_{vj}) the electronic relaxation rate is the same for all metal sites.³⁵

$$\frac{|J|}{\hbar} \gg \tau_{ej}^{-1} \quad (25)$$

$$\frac{|J|}{\hbar} \ll \tau_{vj}^{-1} \quad (26)$$

This case holds for FeS clusters. See⁶ and³⁵ for more details. Although detailed analyses of nuclear and electronic relaxation in coupled systems are few, equation (24) has been of great utility in providing distance constraints for solution structure determination.^{36–39}

3.2 Applications to Fe–S Cluster Proteins

3.2.1 [2Fe–2S] Clusters

[2Fe–2S] proteins can be divided into two classes: 2Fe ferredoxins (Fds), in which each Fe is ligated by two Cys residues, and Rieske proteins, in which one Fe is ligated by two Cys and the other by two His.^{40,41} The 2Fe Fds can be subdivided further into several types, two of which have been studied by NMR: plant-type and hydroxylase-type. In the oxidized state of both types, the ¹H hyperfine-shifted resonances are extremely broad and unresolved. The Cys H^β and H^α protons have been assigned by selective labeling, as have the Cys C^β and N resonances (Table 5).^{42–44} All the

hyperfine resonances move to higher frequency with increasing temperature or exhibit little temperature-dependence.

The electronic structure of the reduced state is very highly conserved among plant-type 2Fe Fds, based upon EPR, Mössbauer, and other studies.^{45–48} Similar studies on reduced hydroxylase-type 2Fe Fds indicate that they, too, have a very highly conserved spectral signature that differs considerably from that of plant-type Fds,^{45–48} despite their very similar geometries in the oxidized state (cf., e.g.,⁴⁹ and⁵⁰). In the plant-type Fds, the hyperfine resonances are far narrower in the reduced state than in the oxidized state, thus facilitating their assignment. In reduced *Anabaena* PCC7120 vegetative Fd, extensive assignments were obtained for the Cys H^β, H^α, C^β, and N resonances through selective labeling, 2D NOESY (tailored for fast-relaxing resonances), 2D ¹H{¹³C} HSQC, and 1D heteronuclear decoupling experiments (Table 5).^{43,44,51} The ¹H NMR spectrum is shown in Figure 4(a).

One very important conclusion from these studies is that the [2Fe–2S]⁺ cluster is valence trapped even at room temperature on the NMR timescale and that the electron resides entirely on the Fe ligated to Cys 41 and 46.⁵² This is consistent with, although not necessarily predicted by, the large negative

value of J_{eff} that has been measured by magnetic susceptibility and temperature-dependent EPR. Less work has been done on reduced hydroxylase-type Fds. Partial assignments derived from selective ^2H labeling are available for human Fd: H^β resonances occur at 103, 80, -10 , and -15 ppm, and H^α resonances at 37 and 13 ppm.⁴⁴ As in the case of plant-type Fds, these data indicate valence-trapping.

A theoretical model was developed by Dunham⁵³ and later extended by Banci and Bertini^{32,54} by use of equation (23) to explain the sign, magnitude, and temperature dependence of the chemical shifts of the ^1H hyperfine resonances in reduced Fds. In this model, the intrinsic hyperfine coupling constants

for Cys H^β and H^α protons were assumed to be 1.0 and 0.1 MHz, respectively, and to be only coupled to the closer of the two Fe sites; thus, J_{eff} becomes the only scalable parameter. From magnetic susceptibility and temperature-dependent EPR, J_{eff} is approximately -100 cm^{-1} in plant-type Fds^{46,55–59} and -250 cm^{-1} in hydroxylase Fds.^{45,46,59} Remarkably good agreement with this model is obtained for the ^1H hyperfine data on plant-type Fds, but only if J_{eff} is assumed to be half the experimental value (Figure 5(b)).

In this case, at room temperature, the H^β and H^α protons on the Fe^{3+} side are predicted to be at 123 and 17 ppm, respectively, and to shift to lower frequency with increasing

temperature, and the H^β and H^α protons on the Fe^{2+} side are predicted to be at 26 and 7 ppm, respectively, and to shift to higher frequency with increasing temperature. Qualitative agreement is found for the hydroxylase-type Fds using the experimental value for J_{eff} : the H^β and H^α protons on the Fe^{3+} side are predicted to be at 67 and 11 ppm, respectively, and to shift to lower frequency with increasing temperature, and the H^β and H^α protons on the Fe^{2+} side are predicted to be at -29 and 1.5 ppm, respectively, and to shift to higher frequency with increasing temperature (Figure 5(b)). The model breaks down when comparing temperature dependence of the ^{15}N and ^{13}C hyperfine shifts, where there is not a clear pattern of two resonances shifting to higher frequency and two to lower frequency. A similar approach can be used for understanding the hyperfine shifts in $[2Fe-2S]^{2+}$ clusters. Since in this case the g.s. is $S = 0$, only thermal population of paramagnetic excited states yields hyperfine shifts. Here J is large (-175 cm^{-1}),⁴⁶ so all of the resonances shift to higher frequency with increasing temperature

as the population of paramagnetic excited states increases (Figure 5(a), solid lines).⁵⁴ Overall, the success of the vector coupling model in qualitatively explaining hyperfine shifts in $[2Fe-2S]$ clusters justifies its use in more complex systems.

Among the Rieske proteins, the one from the toluene-4 monooxygenase system of *P. mendocina* (TMOC) is the best characterized by NMR. In the reduced state, the 1H spectrum exhibits five resonances at high frequency (Figure 4(b), Table 5) that have been assigned as Cys H^β and His $H^{\epsilon 1}$ protons based upon selective 2H labeling.⁶⁰ This study also provided a thorough examination of the ^{15}N hyperfine shifts of H-bonded N nuclei.⁶⁰ In both the redox states, six amide and two His $H^{\epsilon 2}$ N nuclei were found to exhibit paramagnetic shifts and were assigned by selective ^{15}N -labeling. Four of these are H-bonded to the $[2Fe-2S]$ cluster in the crystal structure of a homologous Rieske protein. The crystal structure also showed a fifth amide that was H-bonded to the cluster, but the homologous residue in this system did not exhibit any

hyperfine shift. The origin of the hyperfine shifts in Rieske proteins has not yet been analyzed in detail.

3.2.2 $[3\text{Fe}-4\text{S}]$ Clusters

The $[3\text{Fe}-4\text{S}]$ clusters that have been studied by NMR are found in two types of proteins: 3Fe Fds and 7Fe Fds. The 3Fe Fds are formed from Fds that contain one $[4\text{Fe}-4\text{S}]$ cluster in which one Fe is labile and is readily removed to yield a stable $[3\text{Fe}-4\text{S}]$ cluster. The 7Fe Fds contain one $[3\text{Fe}-4\text{S}]^+$ cluster and one $[4\text{Fe}-4\text{S}]^{2+}$ cluster, in which only the former can be readily reduced. The hyperfine-shifted ^1H resonances in $[3\text{Fe}-4\text{S}]^+$ clusters have substantially narrower linewidths than in $[2\text{Fe}-2\text{S}]^{2+/+}$ clusters. Hyperfine-shifted signals from $[3\text{Fe}-4\text{S}]^+$ clusters have been extensively assigned by 1D NOEs, 2D NOESY, 2D magnitude COSY, and 2D TOCSY. In all cases, the Cys H^β resonances are found in the 35 to -1 ppm range; some shift to higher frequency with increasing temperature and some to lower frequency. A representative example is *D. gigas* 3Fe Fd (Figure 4(c), Table 5).⁶¹

The chemical shifts and temperature dependencies of the hyperfine-shifted resonances are readily understood using the vector coupling model outlined above. The pattern of hyperfine-shifted resonances depends upon the relative values of the three exchange coupling parameters, J_{12} , J_{13} , and J_{23} .

From Mössbauer⁶² and temperature-dependent EPR,^{63,64} all J -values are close in magnitude but not equal. From magnetic susceptibility, J is large and negative ($|J| > 100\text{ cm}^{-1}$).⁶⁵ S_2 and S_3 are coupled to yield spin S_{23} , which ranges from 0 to 10, and S_{23} is coupled with S_1 to yield states of the form $|S_{23}, S\rangle$.⁶² One can consider three cases.^{66–70} (1) If $|J_{12}| = |J_{13}| < |J_{23}|$, then $|2, 1/2\rangle$ is the g.s., and one expects one pair of Cys H^β protons to exhibit large high-frequency shifts that decrease in frequency with increasing temperature since they are coupled to the larger spin ($S_1 = 5/2$), and the other two pairs of Cys H^β protons exhibit smaller high-frequency shifts that increase in frequency with increasing temperature (Figure 5(c), solid lines). (2) If $|J_{12}| = |J_{13}| > |J_{23}|$, then $|3, 1/2\rangle$ is the g.s., and two pairs of Cys H^β protons are expected to exhibit large high-frequency shifts that decrease in frequency with increasing temperature, since they are coupled to the larger spin ($S_{23} = 3$), and the third pair of Cys H^β protons to exhibit low-frequency shifts that increase in frequency with increasing temperature (Figure 5(c), dashed lines). (3) In the intermediate case, $|J_{12}| > |J_{13}| > |J_{23}|$, the g.s. is a mixture of $|2, 1/2\rangle$ and $|3, 1/2\rangle$, and one pair of Cys H^β protons will have high-frequency shifts that decrease with temperature, one will have minor hyperfine shifts that increase in frequency with temperature, and the third will be slightly shifted to higher frequency and weakly temperature-dependent, with the direction dependent on the exact strength of the coupling.^{66–70} Indeed, this range of behavior has been observed. The 3Fe Fds of

D. gigas^{61,67} and *T. litoralis*^{66,71} and the 7Fe Fds from *D. ambivalens*,⁶⁸ *Sulfolobus* sp. Strain 7,⁷² and *S. acidocaldarius*⁷³ are examples of the first case. Most of the other 7Fe Fds exhibit behavior of the third type^{69,70,74–78} *Pyrococcus furiosus* 3Fe Fd is somewhat different in that the two Cys H^β protons that shift to lower frequency with temperature are at slightly lower frequency than in other [3Fe–4S] clusters and have a much larger chemical shift difference between them (23.6 and 11.8 ppm).^{66,79} This was originally ascribed to magnetic coupling of the first type, but with the $S_1 = 5/2$ Fe ligated to Cys11 (equivalent to Cys8 in *D. gigas*) rather than Cys56 (equivalent to Cys50) as is found in other 3Fe Fds;⁷⁹ however, this interpretation has recently been challenged.^{70,73} In *Desulfovibrio africanus* 7Fe Fd, four resonances were found at high frequency that moved to lower frequency with increasing temperature. This would appear to be an example of the case where $|J_{12}| \approx |J_{13}| > |J_{23}|$; however, detailed assignments were not reported, and no signals were found at frequencies below the diamagnetic region as expected from the above model. Thus, in the [3Fe–4S]⁺ clusters, the vector coupling model has provided a firm basis for beginning to understand how differences among proteins modulate electronic structure.

For many years, there were essentially no reports on the hyperfine-shifted resonances in [3Fe–4S]⁰ clusters, despite an attempt to selectively ²H-label the Cys residues⁸⁰ and exploit the slower relaxation rate expected for ²H, as had been done for CpRd.¹⁰ [3Fe–4S]⁰ clusters are a case where double exchange must be considered, and it was revealed by Mössbauer that the coupling could be viewed as mixed-valent iron pair in which double exchange exceeds the effects of isotropic exchange, vibronic coupling, and static asymmetry to yield a valence-delocalized (i.e., 2Fe^{2.5+}) $S_{23} = 9/2$ state that is in turn coupled to the remaining Fe³⁺.⁸¹ In the simplest model (all J -values are equal), the Hamiltonian describing this is:

$$\mathcal{H} = -2J \sum_{i < j=1-3} \mathbf{S}_i \cdot \mathbf{S}_j \pm B \left(S_{23} + \frac{1}{2} \right) \quad (27)$$

yielding energies for the total spin states of

$$E(S) = -JS(S+1) \pm B \left(S_{23} + \frac{1}{2} \right) \quad (28)$$

From Mössbauer, the g.s. is $|9/2, 2\rangle$ which indicates that $B > 4|J|$.⁸¹ It is likely that the location of the valence-delocalized Fe^{2.5+} pair can exchange among the three irons, and such an exchange, with a rate constant of $\sim 10^5$ – 10^6 s^{−1}, was invoked as the reason the hyperfine-shift Cys resonances were not observed.⁸² Indeed, a new signal appears in the Mössbauer spectrum at higher temperatures (150 K) that indicates that all Fe sites are equivalent as a result of complete delocalization of the extra electron.⁸¹ Reduction of the [3Fe–4S]⁺ cluster at neutral pH is believed to involve protonation of the μ -sulfido bridges. Thus, chemical exchange resulting from dynamic protonation/deprotonation of the sulfides could provide the mechanism for signal broadening. Consistent with this view is the observation of very broad hyperfine-shifted NMR signals at high pH, where the protonation/deprotonation mechanism should be minimal. These signals, shifted both to higher and lower frequencies by 100–300 ppm have been preliminarily assigned to Cys H^β protons (Table 5).⁸²

3.2.3 [4Fe–4S] Clusters

[4Fe–4S] clusters have been extensively studied by NMR, much more so than all of the other classes of FeS proteins, in part because their relatively narrow hyperfine-shifted signals greatly aid in sequence-specific assignment. As listed in Table 3, they can exist in three different redox states. The [4Fe–4S]³⁺ state is found in the oxidized HiPIPs. In most of these, the protons of the ligating Cys residues have been extensively assigned by 1D NOEs, 2D NOESY, 2D magnitude COSY, 2D TOCSY, 1D saturation-transfer, and 2D EXSY. Representative ¹H NMR data from *E. halophila* HiPIP I is given in Figure 4(d) and Table 6; the latter also lists ¹³C and ¹⁵N data obtained from 2D experiments.^{38,83,84}

In the oxidized HiPIPs, the Cys H^β resonances are found throughout the 150 to −70 ppm range and vary significantly among different HiPIPs, despite their close structural homology. In all cases, however, four Cys H^β resonances shift to lower frequency with increasing temperature, and four to higher frequency. To understand this behavior it is necessary to first consider the case of *E. halophila* HiPIP II. This is the only HiPIP that exhibits four Cys H^β resonances at high field (95–45 ppm) that shift to lower frequency with increasing temperature and four at low field (−10 to −25 ppm) with the opposite temperature-dependence.^{85–87} From Mössbauer, the oxidized HiPIPs consist of a Fe³⁺ pair and a valence-delocalized Fe^{2.5+} pair that are coupled to yield a net $S = 1/2$ g.s.,^{88–90} as also shown by EPR.^{54,90,91} Noodleman explained this behavior based upon the following Hamiltonian:

$$\mathcal{H} = \sum_{i < j=1-4} -2J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j \pm B_{34} \left(S_{34} + \frac{1}{2} \right) \quad (29)$$

where S_1 and S_2 are the spins of the Fe³⁺ pair and S_3 and S_4 are the spins of the Fe^{2.5+} pair ($S_1 = S_2 = 5/2$ and $S_3, S_4 = 5/2, 2$).^{34,92,93} Since J_{12} is the Heisenberg exchange coupling parameter for the Fe³⁺ pair, it is assumed to be the largest. B_{34} is the double exchange term for the valence-delocalized Fe^{2.5+} pair. This then yields the following for the energies of the total spin states:

$$E(S) = -JS(S+1) - \Delta J_{12} S_{12}(S_{12}+1) \pm B_{34} \left(S_{34} + \frac{1}{2} \right) \quad (30)$$

where $J = J_{13} = J_{14} = J_{23} = J_{24} = J_{34}$ and $\Delta J_{12} = J_{12} - J$. There are multiple states with total spin $S = 1/2$. Based upon single-crystal X-band ENDOR data on a [4Fe–4S]³⁺ model complex with very similar Mössbauer and EPR spectral properties, the correct g.s. is $|7/2, 3, 1/2\rangle$ (nomenclature is $|S_{34}, S_{12}, S\rangle$).⁹⁴ With $J_{12} > J$, this requires $6 < B_{34}/\Delta J_{12} < 8$.⁹⁵ With the same vector coupling model (see below), $J = -130$ cm^{−1}, $J_{12} = -162$ cm^{−1}, and $B_{34} = 250$ cm^{−1} yields qualitatively correct agreement with the behavior of the Cys H^β resonances of *E. halophila* HiPIP II (Figure 5(d)).^{32,86,96,97} In a slightly more sophisticated model in which $J_{34} \neq J$, B_{34} and J_{34} are covariant, and hence it currently is not possible to determine any of the parameters independently. This has led to considerable debate as to the exact values to use for the Heisenberg and double exchange parameters.^{95,98} Regardless, the picture remains the same: signals of the Cys ligated to the Fe^{2.5+} pair will be shifted to higher frequency and those ligated

^a298 K.^bThese values were not reported in tabulated form, but were read off the published spectrum⁸⁴ and are therefore approximate.

to the Fe³⁺ pair will be shifted to lower frequency. ¹H hyperfine data of the other HiPIPs, in which only two resonances are at lower frequency than the diamagnetic region, have been explained by invoking a spin equilibrium mechanism, in which the location of the delocalized Fe^{2.5+} pair alternates between two different sets of Fe atoms with the exchange rapid on the NMR timescale.⁹⁹ Based upon the *E. halophila* HiPIP I sequence, Cys 33, 36, 50 and 66 are designated I, II, III, and IV, respectively. In *E. halophila* HiPIP II, Cys I and IV ligated to the Fe³⁺ pair and Cys II and III are ligated to the delocalized Fe^{2.5+} pair. All other HiPIPs exist in equilibrium between this arrangement and a second one, in which Cys I

and II are ligated to the Fe³⁺ pair and Cys III and IV are ligated to the delocalized Fe^{2.5+} pair. Thus, in *E. halophila* HiPIP I, Cys II experiences ~20% Fe³⁺ character, and Cys IV ~20% Fe^{2.5+} character. The degree in which the delocalized Fe^{2.5+} pair is found ligated to Cys III and IV increases in the order *E. halophila* iso I, *R. globiformis*, *E. vacuolata* iso I, *E. vacuolata* iso II, *C. vinosum*, *R. gelatinosus*, and *R. fermentans*. In the last two HiPIPs, Cys II experiences ~70% Fe³⁺ character, and Cys IV ~70% Fe^{2.5+} character.^{100,101} This spin equilibrium model also explains the noticeable deviation in linearity in the temperature dependencies of the Cys H^β protons in *E. vacuolata* HiPIP II, behavior that is not readily accounted for

by other models.⁹⁹ In addition, the EPR spectra of oxidized HiPIPs exhibit a mixture of $S = 1/2$ species in all cases except *E. halophila* iso II. These results have been described in terms of the same model as given above, where now the two species are either frozen out or are exchanging on a timescale slower than the EPR experiment.⁹⁹ The vector coupling picture and the spin equilibrium model provide a remarkably reliable basis for understanding a range of features seen among the oxidized HiPIPs. The exception again is the failure of the simple vector coupling picture to explain the hyperfine shifts of ^{13}C nuclei, in particular the Cys C^α resonances.³⁸

The $[\text{4Fe-4S}]^{2+}$ state is found among all $[\text{4Fe-4S}]$ proteins: HiPIPs, the 4Fe, 7Fe, and 8Fe ferredoxins (which in the oxidized state contain 2 $[\text{4Fe-4S}]^{2+}$ clusters), and two other systems that have been examined by NMR, the nitrogenase Fe-protein and the PsaC subunit of photosystem I. The Cys protons are found in the 22–0 ppm range and always increase in frequency with increasing temperature. In a number of systems, they have been sequence-specifically assigned by the usual assortment of 1D and 2D NMR experiments. Representative data from cluster I of the *C. acidi-urici* 8Fe Fd is given in Figure 5(e) and Table 6.¹⁰² The $[\text{4Fe-4S}]^{2+}$ cluster consists of two nearly identical $\text{Fe}^{2.5+}$ pairs that are antiferromagnetically coupled to yield a net $S = 0$ g.s., as shown by Mössbauer spectroscopy on reduced HiPIPs,^{88,89} oxidized 8Fe and 4Fe Fds,^{103–105} and oxidized nitrogenase Fe-protein.¹⁰⁶ Thus, as in the case of the $[\text{2Fe-2S}]^{2+}$ clusters, the hyperfine shifts arise solely from thermal population of paramagnetic excited states. This behavior can be readily fit by using a Hamiltonian of the sort in equation (29) and adding another $B_{12}(S_{12} + 1/2)$ term to account for double exchange in the second valence-delocalized $\text{Fe}^{2.5+}$ pair.^{34,93,96,97,107} In the simplest possible model all J -values are equal, yielding the following for the energy of the total spin states:

$$E(S) = -JS(S+1) \pm B_{12}\left(S_{12} + \frac{1}{2}\right) \pm B_{34}\left(S_{34} + \frac{1}{2}\right) \quad (31)$$

This readily accounts for the observed hyperfine shifts of the Cys H^β resonances (Figure 5(a), dashed lines).^{96,97,107}

The $[\text{4Fe-4S}]^+$ state occurs in the reduced 4Fe and 8Fe ferredoxins, nitrogenase Fe-protein, and PsaC subunit of photosystem I. The Cys protons are found in the 65 to –5 ppm range and exhibit a mixture of temperature-dependent behavior: some shift to higher frequency and some to lower frequency with increasing temperature. Representative data from cluster I of the *C. acidi-urici* 8Fe Fd is given in Figure 5(f) and Table 6.¹⁰² In this system and a number of others, the Cys protons have been sequence-specifically assigned by 1D and 2D NMR experiments and in particular, with the use of 2D EXSY and existing assignments of the oxidized form.^{102,108} In reduced *C. acidi-urici* 8Fe Fds and in most other cases, the H^β resonances of two Cys residues shift to higher frequency with increasing temperature, and the other two to lower frequency, and all occur in roughly the same chemical shift range.^{102,108} Mössbauer spectroscopy indicates that the $[\text{4Fe-4S}]^+$ cluster consists of a Fe^{2+} pair and a valence-delocalized $\text{Fe}^{2.5+}$ pair.^{103–106,109} In general, the g.s. is $S = 1/2$, although there are notable exceptions, discussed below.⁴⁷ The exchange coupling in the $[\text{4Fe-4S}]^+$ cluster is significantly more complex than in other FeS clusters. The decrease in the average valence of the four Fe atoms leads

to a decrease in the magnitude of J , which in turns means that B has a proportionally greater influence and that the total spin states are closer in energy.^{34,93,110–113} Nonetheless, some insight may be gained by the same simple model as used in equations (29) and (30), where now S_1 and S_2 are the spins of the Fe^{2+} pair and S_3 and S_4 are the spins of the $\text{Fe}^{2.5+}$ pair ($S_1 = S_2 = 2$ and $S_3, S_4 = 5/2, 2$). With reasonable estimates for J and B_{34} one obtains the qualitatively correct behavior of the Cys H^β resonances: those ligated to the $\text{Fe}^{2.5+}$ pair shift to lower frequency with increasing temperature and those ligated to the Fe^{2+} pair shift to higher frequency, and all of them will be higher frequency than the diamagnetic region (Figure 5(f)).

P. furiosus 4Fe Fd is an unusual case. First, one of the ligands to the cluster is an Asp instead of a Cys. Second, the g.s. is a physical mixture of $S = 3/2$ and $S = 1/2$ species based upon EPR.¹¹⁴ The temperature dependencies of the hyperfine-shifted resonances in the reduced state are complex and very unusual; for example, the H^β protons of Cys17 exhibit *opposite* temperature dependence.^{115–117} In contrast, the D14C mutant exhibits hyperfine behavior extremely similar to those of other 4Fe and 8Fe Fds; specifically, the H^β protons of Cys11 and 17 shift to lower frequency with increasing temperature and are assigned to the $\text{Fe}^{2.5+}$ pair, and Cys14 and 56 shift to higher frequency and are assigned to the Fe^{2+} pair.¹¹⁶ Similarly, from EPR, the g.s. is purely $S = 1/2$.¹¹⁸ The unusual hyperfine temperature-dependent behavior observed in the wild-type was explained by invoking a spin-equilibrium model similar to that for the oxidized HiPIPs. In one arrangement, Cys 14 and 56 ligate the $\text{Fe}^{2.5+}$ pair and Cys 11 and 17 the Fe^{2+} pair, and in the other, Cys 14 and 17 ligate the $\text{Fe}^{2.5+}$ pair and Cys 11 and 56 the Fe^{2+} pair, indicating that Asp stabilizes the mixed-valence $\text{Fe}^{2.5+}$ pair.¹¹⁶ Notably, the hyperfine shifts and relaxation rates of the ligand protons in the wild-type protein are not significantly different from other $[\text{4Fe-4S}]^+$ clusters, leading to the conclusion that the presence of $S = 3/2$ species in the EPR spectrum is an artifact of freezing and that in solution the g.s. is purely $S = 1/2$.¹¹⁵ A similar picture exists for the nitrogenase Fe-protein, which also exists as a mixture of $S = 3/2$ and $S = 1/2$ species based upon EPR and Mössbauer.^{106,109} Addition of urea increases the fraction of the $S = 3/2$, and addition of ethylene glycol decreases it.¹⁰⁶ Again, the NMR spectra are not significantly different from those of other $[\text{4Fe-4S}]^+$ clusters.^{119,120} Indeed, the addition of urea or ethylene glycol had little effect, leading to the conclusion that in solution the g.s. is purely $S = 1/2$.

4 CONCLUDING REMARKS

The last decade has seen a dramatic increase in our understanding of electron–nuclear interactions. We have progressed from merely noting the different sorts of the hyperfine-shifted resonances in paramagnetic proteins to being able to accurately calculate them. Relaxation rates are now often used as distance constraints in solution structure determination. The use of residual dipolar couplings holds similar promise. The vector coupling model has been enormously successful in explaining the ^1H hyperfine data in FeS clusters and has contributed greatly to our understanding of the exchange coupling in these complex systems. Further refinement of this model to help better explain ^{13}C and ^{15}N hyperfine data is needed and may lead

to further insights. With these tools in hand, NMR will be capable of answering detailed questions regarding how H-bonds and other aspects of the protein matrix tune the properties of metal active sites and thus their function. Thus, while paramagnetic NMR already is acknowledged as one of the most powerful spectroscopic methods available for investigating the biophysics of metalloproteins, it is now poised to assume similar importance for studies of metalloprotein biochemistry.

Biographical Sketches

Timothy E. Machonkin, b 1971, B.S. Chemistry, 1993, Ph.D., 2000, Stanford University. Dr. Machonkin has been working in the area of bioinorganic chemistry since an undergraduate. In the laboratory of Prof. Edward Solomon at Stanford, he was involved in spectroscopic studies of metalloproteins and model systems, and in particular, EPR and magnetic susceptibility of Cu-containing systems. Since joining the laboratory of Prof. Markley, he has worked on NMR of FeS systems and the development of new methods to study paramagnetic systems with slow electronic relaxation rates by NMR.

John L. Markley, b 1941, B.A. Chemistry, 1963, Ph.D., 1969, Harvard University. Dr. Markley is Steenbock Professor of Biomolecular Structure in the Department of Biochemistry at the University of Wisconsin-Madison. He is Head of the National Magnetic Resonance Facility at Madison and the BioMagResBank, the international repository for biomolecular NMR data. Recently, he became Director of the Center for Eukaryotic Structural Genomics at the University of Wisconsin-Madison.

Electron–Nuclear Multiple Resonance Spectroscopy

1 INTRODUCTION

The term ‘pulsed electron–nuclear multiple resonance’ (PE NMR) spectroscopy refers to a broad range of experimental methods in which pulsed NMR techniques are combined with pulsed electron paramagnetic resonance (EPR) techniques. This combination provides the capability to measure the spectra and spin dynamics of nuclei which are magnetically coupled to unpaired electrons by the hyperfine interaction. Related experimental techniques for measuring the interactions of nuclei coupled to unpaired electrons are paramagnetically shifted NMR, dynamic nuclear polarization (DNP), electron spin resonance (ESR), the pulsed ESR technique of electron spin echo envelope modulation (ESEEM), and continuous wave (CW) electron–nuclear double resonance (ENDOR). These techniques are complementary rather than competing methods for measuring different aspects of the magnetic interactions of the coupled electron–nucleus spin system. Each technique offers certain advantages as well as certain limitations. The most appropriate experimental approach for a given problem also depends on the type of information desired.

The PE NMR techniques discussed in this article are best suited for measuring the magnetic interactions of nuclei in the local coordination structure of a paramagnetic electron. A distinguishing characteristic of nuclei which are detected in PE NMR experiments is that the NMR transition frequencies are shifted by very large values when compared with NMR spectra of diamagnetic samples. These large shifts arise from the large local magnetic fields originating from the unpaired electron spins. Consequently, the resonance frequency is described by the hyperfine coupling and is measured in units of kilohertz or megahertz as opposed to a resonance frequency shift of parts per million referenced to the nuclear Larmor frequency of a standard.

Nuclei which experience large local magnetic fields originating from unpaired electrons are encountered in a wide spectrum of research areas, including chemistry, materials science, polymer science, environmental science, and the biological sciences. Specific examples include: organic and inorganic radical molecules;^{1–3} fossil fuels;^{4,5} organic conductors, semiconductors and electroactive polymers; organometallic transition metal complexes;^{6,7} dopants and other localized states

in semiconductors;⁸ surfaces such as on oxides and semiconductors; at the internal interfaces of semiconductors, superlattice structures, polymers, and composite materials; catalysis; transition metal ions in zeolites; and at the active sites for electron transfer or substrate binding in metalloproteins and metalloenzymes.⁹

If the unpaired electron spins can be treated as independent (or only weakly coupled) dipoles, their magnetic susceptibility is described by paramagnetism. Nuclei which sustain a hyperfine coupling with such electrons are therefore also referred to as paramagnetically coupled nuclei. Under certain conditions the NMR spectrum of paramagnetically coupled nuclei can be observed directly in the NMR spectrum as a paramagnetic shift. This is usually identified by the magnitude of the frequency shift and its temperature dependence. The local magnetic field originating from the unpaired electron spin shifts the NMR frequency and broadens the linewidth for those nuclei which sustain a hyperfine interaction. Both the magnitude of the frequency shift and the linewidth depend on the magnitude of the hyperfine coupling and on the details of the spin dynamics, specifically on the spin relaxation rates of the electron and nuclei. Well-resolved NMR lines can be observed if the electron spin–lattice relaxation time T_{1e} , or electron spin correlation time τ_e , which describes the time dependence of the local magnetic field, is short enough to assure that the orientation dependence of the local field is time averaged to its isotropic value. The paramagnetic shift is then determined by the isotropic hyperfine coupling arising from the unpaired spin density on the nucleus. Several texts have been written which describe the theory and applications of NMR to paramagnetic molecules including proteins and enzymes with paramagnetic transition metal ions.^{10–12}

The short electron spin relaxation time required to observe paramagnetically shifted nuclei directly in NMR spectra also typically result in very broad ESR linewidths. In fact, as a rough guide, paramagnetically shifted NMR transitions are usually only observed in cases where the ESR spectrum is too broad to be observed. However, very broad ESR linewidths can also originate from inhomogeneous line broadening, even if the electron spin relaxation times are very long. In either case, if an ESR spectrum is observed, several experimental approaches are potentially applicable for the measurement of the magnetic interactions of the hyperfine coupled nuclei in these cases. These include DNP, ESR, ESEEM, ENDOR, and the extension of the latter to PE NMR.

In DNP spectroscopy the hyperfine coupling is used as a mechanism to enhance the nuclear polarization. The details of the mechanism for this enhancement and the magnitude of the enhancement depend on the details of the hyperfine interaction, particularly on the time dependence of the hyperfine coupling, and on the details of the ESR spectrum, such as the ESR linewidth and relaxation time. The theory and applications of DNP spectroscopy have been discussed in several texts and review articles.^{13–18} (See *Dynamic Nuclear Polarization and High-Resolution NMR of Solids*.) Here we discuss only those aspects of DNP spectroscopy that are relevant for comparison and contrast with the related techniques mentioned above.

In DNP spectroscopy the NMR signal is detected directly. The ESR transition is used only as a source for achieving enhanced nuclear polarization. Theoretically a maximum enhancement of the NMR signal of the order of ω_e/ω_n can be achieved, but in practice significantly lower values are

usually observed. Direct detection of the NMR signal has the advantage that the high resolution of NMR spectroscopy is maintained. At the same time, this excludes from detection those nuclei which have large hyperfine couplings. This is a result of the combination of low sensitivity and the large shift in transition frequencies. DNP spectroscopy has been applied most successfully in cases where the ESR spectrum consists of a narrow line which is easily saturated. Examples include studies of fossil fuels¹⁹ and polymer interfaces.^{20–22}

Paramagnetically coupled nuclei may be observed directly as hyperfine splittings in the ESR spectrum. Such splittings are often observed in ESR spectra of organic radical molecules in liquids (see *Electron–Nuclear Hyperfine Interactions*). However, if the spin dynamics are not in the fast motion limit, hyperfine splittings are generally not resolved because of inhomogeneous line broadening.

Two different general approaches are available for measuring the magnetic couplings of nuclei which are not resolved in the ESR spectra. One approach is ESEEM.^{23–26} In this technique both the allowed and the semiforbidden ESR transitions are coherently excited using two or more short, intense microwave pulses. The nuclear hyperfine and quadrupole interactions (in the case of nuclei with spin multiplicity $I \geq 1$) are observed as a periodic modulation of the envelope of the primary spin echo or stimulated echo intensity. Fourier transformation of this modulation pattern yields a spectrum of frequencies corresponding to the hyperfine (and quadrupolar for $I \geq 1$) frequencies.

One of the advantages of the ESEEM experiment is its high sensitivity, which is roughly comparable with that obtained in an ESR experiment. Furthermore, by selecting the appropriate microwave excitation frequency and applied magnetic field conditions, it is possible to measure the pure nuclear quadrupolar resonance frequencies for nuclei with $I \geq 1$.^{27,28} This is possible despite the fact that the experiment is performed at finite magnetic field and the only spin transitions that are excited are the ESR transitions. One limitation of this type of experiment is that nuclear modulation can only be observed if the hyperfine interaction has finite anisotropic coupling components. The second criterion for modulation to be observed is that the microwave pulses must be able to excite both allowed and semiforbidden ESR transitions. This places constraints on the nature of the hyperfine interaction which will yield observable modulation. The theory, techniques, and applications of ESEEM spectroscopy have been reviewed in several texts and review articles.^{23–27,29}

The second approach for measuring the magnetic couplings of nuclei which are not resolved in the ESR spectra is directly to excite both the NMR and ESR transitions with rf and microwave excitation. The first double resonance experiment of this type, known as an ‘electron–nuclear double resonance’, or simply ENDOR, experiment was reported by Feher in 1956.³⁰ The continuous wave (CW) ENDOR experiment is performed by applying a strong microwave field which is selected to irradiate continuously an EPR transition while simultaneously applying a strong rf field. The rf field is swept through the range of frequencies that encompass the NMR spectrum while continuously observing the intensity of the EPR transition. The intensity of the latter changes whenever the rf frequency matches an NMR transition frequency. The intensity of the EPR transition plotted as a function of the rf frequency generates the ENDOR spectrum. Thus, the

ENDOR spectrum is a spectrum of the NMR transitions detected indirectly via the EPR transition. This is in contrast to the ESEEM experiment where the nuclear spin flip is a consequence of exciting a semiforbidden ESR transition. As a result, anisotropic hyperfine interactions are not necessary to observe hyperfine frequencies in the ENDOR experiment.

The ENDOR technique and applications have been documented in several texts and review articles.^{1,8,9,31–36} In the case of one electron coupled to a spin- $\frac{1}{2}$ nucleus, and considering for simplicity that the hyperfine interaction is isotropic, the ENDOR spectrum comprises two transitions corresponding to one NMR transition for each of the two electron spin states. There exists a one-to-one correspondence between the number of coupled inequivalent nuclei and the number of ENDOR transitions observed. This can be contrasted to the number of transitions observed in the EPR spectrum where the number of transitions observed is a multiplicative function of the number of inequivalent nuclei coupled to the unpaired electron spin. The reduced number of transitions results in spectral simplification and, consequently, in enhanced spectral resolution.

While the success of the CW ENDOR experiment has been well documented, certain inherent problems in the technique have also limited its applicability. One well-documented limitation of the CW ENDOR experiment is the constraints on the relationship between NMR and ESR relaxation rates that must be satisfied in order to observe an ENDOR signal.^{31,32,37–41} These constraints are changed (although not removed) with pulsed excitation techniques. This was recognized by W. B. Mims who reported the first pulsed ENDOR experiment in 1965, roughly a decade after Feher’s initial report of the CW ENDOR experiment. Since then the advantages and applications of employing pulsed excitation techniques for both the ESR and NMR transitions have been demonstrated in publications from several laboratories.^{37,38,41–46}

A second significant advantage of employing pulsed excitation techniques for both the ESR and NMR transitions is the potential for extending the type of experiments which can be performed. This is in many respects analogous to the extension of the experimental capabilities which become possible using pulsed excitation techniques in NMR spectroscopy. There are, however, distinct differences that must be kept in mind when using the analogy to pulsed NMR. These will be discussed in more detail in the next section. Furthermore, since multiple irradiation frequencies may be used to excite both the NMR and EPR transitions, the modern combined pulsed NMR and pulsed EPR experiments will be referred to as ‘pulsed electron NMR’ (PE NMR) spectroscopy. In this article, we describe the basic principles of these techniques, their implementation, including the pulse schemes and specific examples of experimental techniques, and illustrate the type of information that can be derived with examples in selected applications.

2 BASIC PRINCIPLES

In this section the magnetic interactions that determine the frequencies and amplitudes in pulsed ENDOR spectra are briefly reviewed. More comprehensive treatments can be found in several texts.^{2,6,31,32,47,48} The analysis of the pulsed ENDOR spectrum provides the starting point for understanding the extensions of the basic pulsed ENDOR technique. After

the properties of the pulsed ENDOR spectrum have been presented, the general approach for the PE NMR techniques will be introduced. This is followed by specific experimental techniques with examples of applications.

2.1 Nuclear Spin Interactions and the Spectrum

2.1.1 Transition Frequencies

For spin- $\frac{1}{2}$ nuclei, the NMR spectrum of the paramagnetically coupled nuclei is dominated by the local magnetic field generated by the unpaired electron spin and by the applied magnetic field. The magnitude and orientation of this local field depends on whether the electron spin is aligned along or opposed to the direction of the external magnetic field. The effect of the combined local field and applied field on the nuclear spin is described by the nuclear spin Hamiltonian (expressed in units of frequency)

$$\hat{\mathcal{H}}_n = \sum_{i=1}^3 (\hat{\mathbf{S}}' \cdot \mathbf{A} - g_n \beta_n B_0 b_i) \hat{I}_i \quad (1)$$

where the subscript $i = 1, 2, 3$ on $\hat{I}_i$ refers to the x, y, z components of the nuclear spin operator $\hat{\mathbf{I}}$. The prime on the electron spin operator $\hat{\mathbf{S}}'$ indicates that a coordinate system is selected in which the $\mathbf{g}$ tensor is diagonal. The b_i are the unit vectors of the applied magnetic field expressed in spherical polar coordinates:

$$(b_1, b_2, b_3) = (\cos \phi \sin \theta, \sin \phi \sin \theta, \cos \phi) \quad (2)$$

In most pulsed EPR experiments, particularly on transition metal ions, the microwave pulses excite only a small region of the spectrum centered about the magnetic field for resonance. This magnetic field position selects a subset of molecular orientations defined by the resonance condition, $h\nu = g\beta B_0$, where the orientation dependence of the electronic g factor is expressed by

$$g(\theta, \phi) = \left[\sum_{i=1}^3 (g_i b_i)^2 \right]^{1/2} \quad (3)$$

The number of molecular orientations which contribute to the ENDOR spectrum is minimum for values of (θ, ϕ) that correspond to the principal axes of the $\mathbf{g}$ tensor. This phenomenon is referred to as g -factor orientation selectivity.⁴⁹ Since a lower number of molecular orientations contribute, higher spectral resolution can be observed in ENDOR spectra recorded at magnetic field values corresponding to those values of (θ, ϕ) which correspond to these principal axes.

The local field is described by the term $\hat{\mathbf{S}}' \cdot \mathbf{A}$, where $\mathbf{A}$ is the hyperfine interaction tensor. The magnitude of the local field depends on the distance between the electron and the nucleus and on the nature of the chemical bonding that pertains to the electron and nucleus, i.e. on the electronic state in which the electron resides. The distance separating the electron and nucleus determines a classical dipolar interaction. Since the gyromagnetic ratio of the electron is very large, this

local magnetic field can be very large. The classical dipolar field will only provide a valid description of the distance between the electron and nucleus if the electron can be treated as a point dipole. Contributions to the hyperfine anisotropy also depend on the nature of the electronic wavefunction. The latter also determines whether the nucleus has a finite unpaired electron spin density at the nucleus. A finite unpaired spin density at the nucleus can only occur if the molecular orbital that describes the unpaired electron has some atomic s-orbital contribution in the wavefunction. The nonclassical contribution to the hyperfine anisotropy is sometimes referred to as 'pseudodipolar coupling'.

The orientation dependence of the local field can be expressed by an orientation-dependent hyperfine coupling $A(\theta, \phi)$. The NMR transition frequencies are then given by

$$\nu_{\pm} = \nu_n \pm \frac{1}{2} |A(\theta, \phi)| \quad (4a)$$

$$\nu_{\pm} = \frac{1}{2} |A(\theta, \phi)| \pm \nu_n \quad (4b)$$

where the first expression applies if $2\nu_n > |A|$ and the second expression applies if $2\nu_n < |A|$, while in both cases it is assumed that $I = \frac{1}{2}$.

The two limiting expressions [equations (4a) and (4b)] for the NMR frequencies are a recognition of the fact that the local magnetic field described by the hyperfine interaction can be comparable to or larger than the applied magnetic field. This is especially the case at the low applied field strengths, typically 0.35 T, at which many ENDOR and PE NMR experiments are performed. If the local field is greater than the applied field, then the local field is the dominant term that defines the nuclear quantization axis and the applied field is a perturbation. In either case, equations (4a) and (4b) indicate that for a nucleus with $I = \frac{1}{2}$, two NMR transitions will be observed in the ENDOR spectrum, with one transition originating from each of the two electron spin manifolds defined by the eigenvalue, $m_{S'}$, of $\hat{\mathbf{S}}'$. These NMR transitions will either be centered on the nuclear Larmor frequency if $2\nu_n > |A|$ or on one-half of the hyperfine coupling if $2\nu_n < |A|$.

In the case of organic radicals, the anisotropy of the g factor can be ignored in the first order analysis of the paramagnetically shifted NMR transitions. The NMR transition frequencies $\nu_{\pm}$ are then given by⁵⁰

$$\begin{aligned} \nu_{\pm} = & [(S_z A_{xx} - \nu_n)^2 \sin^2 \theta \cos^2 \phi \\ & + (S_z A_{yy} - \nu_n)^2 \sin^2 \theta \sin^2 \phi \\ & + (S_z A_{zz} - \nu_n)^2 \cos^2 \theta]^{1/2} \end{aligned} \quad (5)$$

where θ and ϕ are the spherical polar angles relating the applied static field $\mathbf{H}_0$ to the principal axis of the hyperfine tensor (A_{xx}, A_{yy}, A_{zz}). Equation (5) assumes that the high-field approximation is valid where the electron and nuclear spin operators $\hat{\mathbf{S}}$ and $\hat{\mathbf{I}}$ are completely decoupled from the molecular framework and quantized along the applied magnetic field direction. An energy level structure corresponding to an arbitrary selected set of (θ, ϕ) values is shown in Figure 1.

In general, the g factor for the electron will not be isotropic as assumed in the expressions described by equations (4a), (4b) and (5). Anisotropy of the electron g factor is usually

significant in ESR spectra of transition metal ions.^{6,7} If the g factor is anisotropic, the NMR frequencies and lineshape will depend on the magnetic field position and microwave frequency selected.^{6,48,51,52} In a noncrystalline solid, a single pair of NMR transitions will only be observed if the principal axes of the $\mathbf{g}$ and $\mathbf{A}$ matrices are collinear. Otherwise a powder pattern lineshape will be observed because of the angular dependence of the $\mathbf{g}$ and $\mathbf{A}$ matrices.

The NMR frequencies described in equation (5) do not account for the second-order frequency shifts of the ENDOR lines observed for large hyperfine couplings. Since these second-order frequency shifts are proportional to $A^2/4\nu_e$, they can usually be ignored under most experimental conditions. However, even for relatively small hyperfine coupling values, these second-order effects, arising from the spin Hamiltonian terms $\hat{S}_x\hat{I}_x$ and $\hat{S}_y\hat{I}_y$ must be included to calculate correct wave functions that reproduce the rf frequency dependence of the ENDOR amplitudes. These spin coupling terms lead to an enhancement, known as the ‘hyperfine enhancement’, of the rf field seen by the nucleus. Note that the enhancement can also be negative, i.e. a decrease in the rf field at the nucleus, depending on the eigenvalue m'_S of $\hat{S}'$.

The simple four-level system with isotropic hyperfine coupling described by the spin Hamiltonian:

$$h^{-1}\hat{\mathcal{H}}_0 = \nu_e\hat{S}_z - \nu_n\hat{I}_z + a\hat{S}_z\hat{I}_z \quad (6)$$

is usually adequate for describing the basic concepts for the sublevel polarization transfer experiments as well as several other PE NMR experiments described later in this article. In the high temperature limit, i.e. $g_e\beta_e B_0/kT \ll 1$, the spin eigenvalues, $h^{-1}E_0(M_S, M_I)$, are given by:

$$h^{-1}E_0(M_S, M_I) = \nu_e M_S - \nu_n M_I + a M_S M_I \quad (7)$$

The energy levels in Figure 1 also describe these eigenstates which arise from the coupling of an $S = I = \frac{1}{2}$ system with isotropic hyperfine coupling. With this level of simplification it is possible to gain considerable insight into the spin dynamics of PE NMR experiments using the spin operator formalism⁴² frequently used in NMR spectroscopy.⁵³

Figure 1 Energy level structure corresponding to the spin Hamiltonian of a four-level system. EPR, ENDOR, and relaxation transitions are identified

In the literature on pulsed ENDOR and PE NMR spectroscopy, the hyperfine splitting of the electron spin eigenstates are referred to as ‘hyperfine sublevels’ or simply as ‘sublevels’. The EPR, NMR, and spin relaxation transitions relevant in the discussion of the ENDOR experiment are identified in Figure 1. The ENDOR transitions indicated in the figure are NMR transitions detected indirectly by the ESR transition. The electron and nuclear relaxation transition probabilities W_e and W_n correspond to effective T_{1e}^{-1} and T_{1n}^{-1} rates; these are also identified in Figure 1. In the analysis of signal amplitudes in the CW ENDOR experiment, the effective rates are the intrinsic rates enhanced by the application of the microwave or rf excitation fields.

If the nuclear spin multiplicity $I \geq 1$, the quadrupolar interaction will result in additional splittings of the hyperfine sublevels. The quadrupolar interaction is described by adding the nuclear self-coupling term, $\hat{\mathbf{I}} \cdot \mathbf{P} \cdot \hat{\mathbf{I}}$ to the spin Hamiltonians of either equation (1) or equation (6). If the principal axes of the $\mathbf{g} \cdot \mathbf{A} \cdot \mathbf{P}$ are collinear and the magnetic field $\mathbf{B}_0$ is oriented parallel to one of these principal axes, the first-order ENDOR frequencies are given by^{2,6,48}

$$\nu_{\text{ENDOR}} = \left| \frac{A_i}{2} \pm \nu_n \pm \frac{3}{2} |P_i| (2m_i + 1) \right| \quad (8)$$

where A_i and P_i denote the principal values of the $\mathbf{A}$ and $\mathbf{P}$ tensors along the i axis. The nuclear transitions in equation (8) are assumed to increase in the nuclear spin quantum number, i.e. $m_I \rightarrow m_I + 1$. It has also been assumed that $(|A| > 2\nu_n > 3|P_i|)$. The principal values of the quadrupolar tensor $\mathbf{P}$ are defined as $|P_{zz}| > |P_{yy}| > |P_{xx}|$. These principal values are related to the magnitude of the quadrupolar coupling constant χ and asymmetry parameter η by

$$\chi = 2I(2I - 1)P_{zz} \quad (9a)$$

$$\eta = \frac{P_{xx} - P_{yy}}{P_{zz}} \quad (9b)$$

According to equation (8), four ENDOR transitions are expected for a nucleus with $I = 1$. However, not all ENDOR transitions may be observed when exciting an ESR transition at a given magnetic field value, since it is possible that each m_I state may be selectively excited. For example, a two-line ENDOR spectrum will be observed if the ESR transition connects the $m_I = 1$ to $m_I = 1$ sublevels of the $m_S = +\frac{1}{2}$ and $m_S = -\frac{1}{2}$ electron spin manifolds.

2.1.2 ENDOR Amplitudes

ENDOR signal amplitudes are proportional to the change in the EPR signal intensity, ΔE , induced by an NMR transition. Since the EPR signal intensity E is proportional to the electron spin susceptibility χ_e , a relative ENDOR susceptibility can be defined by

$$\frac{\Delta \chi_e}{\chi_e} = \frac{\Delta E}{E} \quad (10)$$

The transition frequencies and amplitudes that are described by the time-independent terms in the spin Hamiltonian are independent of the method of exciting and detecting the transitions. However, the dynamic terms of the total spin Hamiltonian that describe the spin system have different effects on the amplitudes in the CW and pulsed experiment. In the CW experiment, the ENDOR signal amplitude depends on the rate at which the ESR and NMR transitions are excited by the applied microwave and rf magnetic fields compared with the rate of intrinsic relaxation pathways that will compete to restore the spin system to thermal equilibrium. Once the spin eigenstates and relaxation rates that connect the eigenstates have been defined, coupled rate equations can be used to model the ENDOR signal amplitude. In contrast, the pulsed ENDOR or ENMR experiment is performed on a timescale which is short compared with the intrinsic spin relaxation rates. The amplitudes can therefore be analyzed without resorting to coupled rate equations.

In the CW experiment, the interplay between the transition intensity induced by the applied magnetic fields and the intrinsic spin relaxation rates is further complicated by the effect of the hyperfine enhancement on the ENDOR amplitudes.^{31,32,50,54} For intense rf fields, the ENDOR amplitudes can be independent of the rf frequency. For very weak rf fields, the ENDOR amplitudes increase with the square of the rf frequency. For intermediate values, the ENDOR amplitudes can be a complex function of the transition moments and relaxation parameters, especially since both the transition moments and the relaxation rates can be orientation dependent.

In pulsed ENDOR experiments, the analysis of the hyperfine enhancement and the effects of the spin relaxation on the ENDOR amplitudes is less complex. The pulsed ENDOR experiment is usually performed on a timescale which is short compared with the electron, nuclear, and the electron–nucleus cross-relaxation rates. In this case the relaxation rates do not influence the relative ENDOR amplitudes. The loss of electron spin polarization by T_{1e} processes during the mixing period (described in Section 2.2) results in a uniform decrease in the signal amplitudes, $\Delta\chi_e/\chi_e$, across the ENDOR spectrum. The hyperfine enhancement of the NMR transition moment is then simply observed as a change in the sublevel nutation angle as a function of rf frequency. The sublevel nutation angle θ_R is given by $\theta_R = \gamma_n \epsilon B_2 t_{rf}$, where ϵ is the hyperfine enhancement factor. If the hyperfine interaction is isotropic, the hyperfine enhancement factor is given by $\epsilon = |1 + m_s a/\nu_n|$. The hyperfine enhancement can be observed directly in EPR detected sublevel transient nutation experiments.^{43,55}

As described in the next section, the pulsed ENDOR experiment can be divided into pulse periods. The ENDOR amplitude is a function of the microwave pulses in the preparation period and detection period as well as of the nutation angle of the sublevel polarization in the mixing period. The latter can be expressed by

$$EA(\nu_{rf}) = \frac{1}{2}(1 - \cos(\theta_{R\pm})) \quad (11)$$

In the limit of small nutation angles, the cosine term can be expanded in a power series:

$$EA(\nu_{rf}) \approx \frac{(\theta_{R\pm})^2}{4} = \frac{(m_s A)^2}{(2\nu_n)^2} = \frac{(m_s)^2}{(2\nu_n)^2} (\nu_{\pm} - \nu_n)^2 \quad (12)$$

Equation (12) explicitly indicates that the Fermi golden rule result for the rf frequency dependence of the transition probability is obtained in the limit of small nutation angle. If the nutation angle is adjusted to correspond to a π pulse at each ENDOR frequency, the ENDOR amplitudes should be independent of the hyperfine enhancement factor. It is straightforward, although time consuming, to measure the sublevel nutation frequency at each ENDOR frequency in the ENDOR spectrum for a quantitative analysis of the ENDOR amplitudes. Additional contributions to the ENDOR amplitudes arise from the effect of hyperfine contrast selectivity in the preparation period and from possible electron–nucleus coherence effects in the detection period.^{37,38} These effects are discussed in more detail in Section 3. Contributions originating from the hyperfine anisotropy^{6,48} and g -factor orientation selectivity^{6,48} will also affect the amplitudes in both the CW and pulsed ENDOR experiments.

2.2 Pulse Schemes

Many of the PE NMR experimental techniques can be understood by analogy to heteronuclear NMR experiments. However, in making this comparison between PE NMR and heteronuclear NMR experiments, some important differences must be recognized. These originate from the fundamental properties of the unpaired electron compared with a nucleus. The two most significant differences are the γ values of the electron and nucleus and the differences between the nature of the wave functions that describe the electron and the nucleus.

The larger γ for the electron compared with any nucleus has two important consequences. The first is the practical consequence for the type of instrumentation required for PE NMR experiments compared with heteronuclear NMR experiments. The heteronuclear NMR experiment requires a transmitter, probe, and receiver capable of handling two (or more) different rf frequencies. In contrast, for the double resonance experiment between the electron and nucleus, the hardware must be capable of handling both rf and microwave frequency components.

A second consequence of the larger γ of the electron is that the local magnetic field generated by the electron is much larger than is generated by any nucleus. This has several consequences on the properties of the spectra observed for nuclei that are coupled to this local field and also has implications on the types of experiments which can be performed. In most cases, PE NMR experiments must be analyzed within the so-called ‘soft pulse limit’, i.e. the bandwidth of the excitation pulses for both the ESR and NMR transitions are much smaller than the spectral bandwidth. In other words, both the ESR and NMR pulses are generally selective excitation pulses. The broad linewidths also exclude certain techniques such as cross polarization in the rotating frame and magic angle spinning which have had such an important impact on NMR of solids from being directly adapted to PE NMR experiments.

The second important difference to bear in mind when comparing PE NMR spectroscopy with pulsed heteronuclear NMR is the difference in the nature of the total wavefunction associated with the electron compared with the nucleus. The electron is generally in an eigenstate, such as an atomic or

molecular orbital, which has a much greater spatial extent than the localized eigenstate which describes the nucleus. This has the consequence that the electron spin is delocalized so that the electron is generally coupled to many more nuclei than would be the case if the electron were represented by a point dipole. The delocalization of the electron spin density in molecular orbitals that have well defined spatial extents can also contribute large anisotropic components to the local (i.e. hyperfine) field. The anisotropy of the hyperfine interaction also assures that the quantization axis for the nucleus does not point in the same direction in the two electron spin eigenstates. This anisotropy in the hyperfine interaction is therefore responsible for the broad spectral widths observed for the NMR transitions and also affects the transitions which are observed, since formally forbidden transitions become ‘semiforbidden’ transitions.

Another consequence of the nature of the electronic states that host the unpaired electron is that spin coupling mechanisms such as the spin–orbit coupling are effective in broadening the ESR linewidth and in enhancing the spin relaxation rate. Both the broad lines and the shorter relaxation times have implications on the types of PE NMR experiments that can be performed.

The pulse sequences employed in PE NMR experiments can be conveniently divided into pulse periods in direct analogy to NMR spectroscopy. With the above-mentioned caveats in mind, the pulse periods can be analyzed by analogy to a pulsed heteronuclear NMR solids experiment within the soft pulse limit, wherein selective excitation is considered in the analysis. The most basic experiment consists of a preparation, mixing, and detection period. The purpose of the preparation period is to create an initial state perturbed from the equilibrium spin polarization established by the conditions of the temperature and external field (as well as by the level structure of the electron–nuclear coupled spin system). In all PE NMR experiments reported to date, one or two microwave pulses are applied to excite ESR transitions in the preparation period.

Two basically different types of PE NMR experiments will be performed depending on whether the microwave preparation pulses have created sublevel nuclear spin polarization or electron spin coherence at the end of the preparation period. The former are the starting points for ESR detected sublevel polarization transfer experiments and for ESR detected nuclear coherence experiments. The latter is the starting point for coherence transfer ENDOR experiments. In this experiment, a single microwave pulse, ideally a $\pi/2$ pulse, creates electron spin coherence in the preparation period.

In the mixing period, one or more rf pulses are applied to manipulate the sublevel polarization or sublevel coherence. The nature of the perturbation determines the type of experiment performed. The mixing period may include an evolution period, again depending on the type of experiment performed. If sublevel nuclear coherence has been created and is to be indirectly observed via the ESR transition intensity, the mixing period must end with a $\pi/2$ rf pulse that converts the sublevel coherence to sublevel polarization.

In the detection period one or more microwave pulses are applied to create electron spin coherence which is detected in the PE NMR experiment. The electron spin transverse magnetization provides a readout of the electron–nucleus longitudinal order. The transverse magnetization can be

detected by a primary spin echo,⁵⁶ a stimulated echo,⁵⁷ or as a free induction signal.⁵⁸ It is also possible to use CW irradiation to detect the transverse electron magnetization⁴² or to detect the longitudinal electron magnetization directly.²⁹

3 EXPERIMENTAL TECHNIQUES WITH SELECTED APPLICATIONS

3.1 ESR Detected Sublevel Polarization Transfer

It is possible to envisage many pulse sequences which create sublevel nuclear spin polarization. The most common methods, shown in Figure 2, are a single microwave pulse which selectively excites one ESR transition or two microwave pulses. The former was first proposed by Davies⁵⁶ and is the starting point for what has become known as the Davies ENDOR experiment. The latter was first proposed by Mims⁵⁷ and is the preparation pulse sequence for the experiment now known as Mims ENDOR.

Referring to Figure 3, the selective excitation of one of the two allowed ESR transitions converts the electron spin polarization, represented by the boxes, into electron–nucleus two-spin longitudinal order. The spin polarization from the nuclear Zeeman and hyperfine interactions is negligible compared with the electron spin polarization and can be ignored. The two spin order refers to the fact that the nuclear spins in both NMR transitions are polarized.

Two spin electron–nucleus longitudinal order can also be created using two selective microwave pulses or two nonselective microwave excitation pulses if an evolution time separates the two pulses.⁴² Sublevel polarization is created from the transverse components of the magnetization that evolves following the first pulse in the local field of the hyperfine interaction. The second pulse converts the transverse magnetization to two-spin longitudinal order. This suggests that the two pulses should be $\pi/2$ pulses for maximum efficiency in creating sublevel polarization. After the second

Figure 2 Davies ENDOR (a) and Mims ENDOR (b) pulse sequences

Figure 3 The transfer of spin polarization during the preparation (a), mixing (b) and detection (c) periods of the Davies ENDOR sequence for the four level system shown in Figure 1

pulse, the net sublevel polarization is approximately $\sin(a\tau/2) \sin(\Omega_S\tau)$, where a is the hyperfine coupling in equation (6) and Ω_S is a resonance offset. Note that no sublevel polarization exists for values $a\tau/2 = n\pi$, where n is an integer. These are known as blind spots in the Mims ENDOR experiment.

For an ESR lineshape which is inhomogeneously broadened, the sublevel polarization created by the microwave pulses in the preparation period burn a hole into the envelope of the ESR absorption lineshape as shown in Figure 4(a). The width of the hole is determined by the excitation bandwidth of the preparation pulse. In the case of two pulse excitation, a serrated pattern of magnetization is superimposed on the hole, as shown in Figure 4(b).

3.1.1 Davies and Mims ENDOR

The pulse sequences for the two most commonly used experiments for the ESR detection of sublevel polarization transfer are shown in Figure 2. The hole-burning effect created by the preparation pulses on an inhomogeneously broadened ESR absorption envelope is shown in Figure 4. The effect of a selective ESR excitation on the electron spin polarization in a four level system described by equation (7) is shown in Figure 3(a). The electron spin polarization associated with these two energy levels will be inverted if the selective microwave pulse is a π pulse. Note that the sublevel longitudinal polarization of both the upper and lower NMR sublevels are not at equilibrium at the end of the preparation period.

In the next step of the pulse sequence, an rf pulse transfers and thereby ‘mixes’ the electron spin polarization between the sublevels. This is shown in Figure 3(b) for an rf pulse on resonance with the upper sublevel. In the hole-burning picture shown in Figure 4, the sublevel polarization transfer corresponds to the transfer of polarization from within the hole to a frequency offset by the value of the hyperfine coupling. This sublevel polarization transfer occurs at frequencies corresponding to the NMR frequency shifted by the hyperfine interaction (see Section 2.1.1).

The sublevel polarization transfer could, in principle, be detected directly as an NMR signal. Indeed, this would correspond to a pulsed DNP experiment. Note, however, that the sublevel polarization transfer has also changed the electron longitudinal polarization of the two ESR transitions. The sublevel polarization transfer can therefore be detected by

Figure 4 EPR spectra of an inhomogeneously broadened line after the preparation period in the Davies ENDOR (a) and Mims ENDOR (b) pulse sequences. (Reproduced by permission of Academic Press from H. Thomann and M. Bernardo, in ‘Methods in Enzymology’, eds. J. F. Riordan and B. L. Vallee, 1993, Vol. 227, Chap. 6)

measuring the change in the ESR transition intensity. This can be accomplished using a variety of techniques, as discussed in Section 2.2. In the Davies and Mims ENDOR pulse sequences the change in electron longitudinal polarization is detected by observing the change in intensity of a primary or stimulated spin echo. This electron spin coherence is indicated by the double arrow in Figure 3(c).

The spectrum of NMR transition frequencies shifted by the hyperfine coupling, i.e. the ENDOR spectrum, usually far exceeds the excitation bandwidth of the rf pulses. The complete spectrum must therefore be recorded by incrementing stepwise the rf frequency on successive iterations of the pulse sequences shown in Figure 2. The limit of resolution in the spectrum is determined by the excitation bandwidth of the rf pulse.

The Davies ENDOR spectrum of a single crystal of malonic acid which has been irradiated by X-rays to generate carbon π radicals⁵⁹ is shown in Figure 5. The transitions at approximately 5 and 30 MHz are the two sublevel transitions associated with the α proton of the CH fragment of the $\cdot\text{CH}(\text{COOH})_2$ radical molecule. The other proton lines originate from the carboxylic protons, from coupling to protons on neighboring malonic molecules, and from overlapping ESR signals from different malonic acid radical molecules.⁵⁹ The increase in spectral resolution obtained by decreasing the excitation bandwidth of the rf mixing pulse is shown in the inset of the figure.

The relative amplitudes of the ENDOR transitions are determined by the spin Hamiltonian (as discussed in

Figure 5 Davies ENDOR spectrum of an X-ray irradiated crystal of malonic acid with rf pulse widths of 5 μ s (a) and 10 μ s (b). (Reproduced by permission of the American Chemical Society from H. Thomann and M. Bernardo, in 'Advances in Chemistry Series 229: Magnetic Resonance of Carbonaceous Solids', eds. R. E. Botto and Y. Sanada, Washington, DC, 1993, Chap. 4)

Section 2.1.2) but also by the excitation bandwidth, Δ_p of the preparation pulse. In order for a sublevel polarization transfer signal to be detected indirectly using the Davies ENDOR pulse sequence [Figure 2(a)], the condition that $\Delta_p > a$, where a is the hyperfine coupling, must be satisfied.⁵⁶ If $\Delta_p > a$, the transfer of polarization remains within the hole burned into the absorption envelope. In this case the change in electron polarization is reduced, resulting in a weaker ENDOR signal. This relationship between Δ_p and a has been referred to as 'hyperfine contrast selectivity',^{37–39} as a 'spin alignment hole',⁴¹ and as a 'self-ELDOR effect'.⁴² The relationship between Δ_p and a can be used to eliminate or reduce the overlap of ENDOR signals originating from nuclei with different hyperfine couplings.^{37–39,60}

Davies ENDOR spectra on a blue copper protein, stellacyanin,⁶¹ will serve to illustrate the application of pulsed ENDOR (and PE NMR) spectroscopy. Transition metal ions and ion clusters are found at the active site for electron transfer in metalloproteins and at the active site for substrate conversion in metalloenzymes. The electron spin echo detected ESR (ED ESR) absorption envelope recorded by plotting the intensity of the primary electron spin echo as a function of magnetic field is shown in the inset of Figure 9. A spectroscopic model for the ligand coordination structure of the Cu^{2+} ion for the high-pH form of the protein is shown in Figure 6. The hyperfine coupling frequencies for each nucleus on the copper ligands are indicated in Figure 6. The NMR transitions for nuclei in the primary ligand coordination

Thomann and M. Bernardo, in 'Methods in Enzymology', eds. J. F. Riordan and B. L. Vallee, London, 1993, Vol. 227, Chap. 6)

Figure 7 Davies ENDOR spectra of stellacyanin using microwave inversion and detection pulse widths t_{mw} of 0.40, 0.20, 0.40 μ s (a) and 0.04, 0.02, 0.04 μ s (b). (Reproduced by permission of Academic Press from H. Thomann and M. Bernardo, in 'Methods in Enzymology', eds. J. F. Riordan and B. L. Vallee, 1993, London, Vol. 227, Chap. 6)

structure of the Cu^{2+} ion would be difficult to measure by any other spectroscopic technique.

The hyperfine contrast selectivity mechanism for eliminating the overlap of ENDOR lines is illustrated in Figure 7, where two Davies ENDOR spectra of stellacyanin⁶¹ are shown. When a preparation pulse with narrow excitation bandwidth is used [Figure 7(a)], the proton ENDOR lines which have small hyperfine coupling values that originate from protons on the two imidazole ligands overlap the nitrogen ENDOR lines, particularly the nitrogen line centered at roughly 8 MHz. When a larger excitation bandwidth is used [Figure 7(b)] the amplitudes for these proton ENDOR lines are significantly attenuated. The 1 : 2 relative intensities of the two ^{14}N ENDOR lines centered at 8 and 18 MHz in Figure 7(b) are in agreement with the expected intensity difference due to the hyperfine enhancement factor.^{37,38}

The proton ENDOR signals from protons with small hyperfine couplings can also be observed using preparation pulses with large excitation bandwidths with the Mims ENDOR pulse sequence. A comparison of the Davies and Mims ENDOR spectra for the stellacyanin protein is shown in Figure 8. The arrows in the Mims ENDOR spectrum indicate the positions of the 'blind spots' where no ENDOR signal is observed. The position of these blind spots in the spectrum

Figure 8 Comparison of the Davies and Mims ENDOR spectra for the stellacyanin protein. (Reproduced by permission of Academic Press from H. Thomann and M. Bernardo, in 'Methods in Enzymology', eds. J. F. Riordan and B. L. Vallee, London, 1993, Vol. 227, Chap. 6)

can be selected by the value of τ chosen in the Mims ENDOR pulse sequence. Note that the ENDOR signal for the protons with small hyperfine couplings is significantly enhanced in the Mims ENDOR spectrum. This is a consequence of the fact that a larger fraction of the electron magnetization can be sampled without suppressing the ENDOR signals from the nuclei with small hyperfine couplings.

An example of the advantage of the increased sensitivity achieved by the indirect detection scheme of the pulsed ENDOR experiment is shown in Figure 9, where the ENDOR signals from the central metal Cu^{2+} ion as well as those from all the (NMR active) ligand nuclei on the metal ligands are observed. The position in the ED ESR spectrum at which this Davies ENDOR spectrum was recorded is shown in the inset of the figure. Although the hyperfine splitting of the Cu^{2+} ion can be observed at the high-field end of the ESR spectrum, the hyperfine splittings are not resolved in the low-field region of

Figure 9 Davies ENDOR spectra of stellacyanin showing the Cu, N, and H resonances. Inset shows the position in the ED ESR spectra where the ENDOR spectra was recorded. (Reproduced by permission of Plenum Press from H. Thomann and M. Bernardo, in 'Biological Magnetic Resonance', eds. L. J. Berliner and J. Reuben, New York, 1993, Vol. 13, Chap. 7)

the ESR spectrum. Note also that the pulsed ENDOR spectrum reveals the quadrupolar splitting of the Cu^{2+} nucleus. It is not possible to measure these quadrupolar interactions in the ESR spectrum.

3.1.2 Transient Nuclear Nutations

The sublevel nuclear transient nutations can be detected indirectly with the pulse sequences in Figure 2 by incrementing stepwise the rf pulse length on successive pulse sequence iterations. An example is shown for the malonic acid radical in Figure 10. The effect of the time dependence of the signal from the electron spin-lattice relaxation during the mixing time can be eliminated by choosing a fixed, long mixing time before detection or by subtracting the signal recorded without the rf pulse applied (or with the rf frequency set to an off-resonance position in the ENDOR spectrum). The electron spin echo amplitude in the detection period oscillates with a periodicity proportional to $\cos \theta_2$ where θ_2 is the sublevel nutation angle (see Section 2.1.2). These oscillations are sometimes referred to as Rabi oscillations. The influence of the hyperfine enhancement factor on the nutation angle is evident in Figure 10.

The sublevel nutation experiment provides a method for setting the rf mixing pulse conditions to the selected nutation angle. For ESR detected sublevel polarization transfer experiments, the optimum pulse is a π pulse. For the ESR detection of sublevel coherence, the rf mixing pulse would be set for a $\pi/2$ pulse. For samples which are not single crystals and that exhibit hyperfine anisotropy, the Rabi oscillations are rapidly damped after the first period.^{37,38} Consequently, the effect on the ENDOR amplitudes due to the hyperfine enhancement can be reduced by selecting a long rf pulse length. However, this produces power broadened lines, and therefore a lower resolution in the spectrum. When two or more magnetically equivalent nuclei are coupled to the electron, harmonics may be observed in the sublevel nutation pattern.⁴² An example is shown in Figure 11. Analysis of these

harmonics provides a method for determining the number of equivalent nuclei coupled to the electron.

3.1.3 Optimized Davies and Mims ENDOR

The Davies or Mims ENDOR pulse sequences produce a maximum ENDOR enhancement of $\Delta\chi_e/\chi_e = 1$. A pulse scheme for theoretically increasing this efficiency to $\Delta\chi_e/\chi_e = 2$ has been proposed and demonstrated.⁴² This is accomplished by inserting a microwave π pulse and a second rf π pulse following the first rf π pulse in the mixing period. This pulse sequence is the pulsed analog of the Special TRIPLE resonance technique which was also introduced to improve the efficiency in the CW ENDOR experiment.^{34,62,63} In practice, the improvement in efficiency of the Davies or Mims ENDOR signal intensity is much smaller than theoretically possible, primarily because of pulse imperfections. Nevertheless, a gain in ENDOR enhancement is observed, as shown in the example given in Figure 12. Nonideal nutation angles due to pulse imperfections are particularly problematic for noncrystalline samples where the ENDOR lines are significantly overlapped.

3.1.4 Electron–Nucleus Coherence Effects

Electron–nucleus coherence effects can be observed in the Davies ENDOR experiment if the microwave pulses in the detection period excite both allowed and semiforbidden ESR transitions.^{38,37} These coherence effects generate a nuclear modulation on the envelope of the primary electron spin echo in the detection period analogous to the ESEEM experiment. An example of this phenomenon is shown in Figure 13 where two Davies ENDOR spectra for the blue copper protein,

Figure 12 Mims-ENDOR spectra (a) of Cu(II)-doped TGS single crystal around the proton transition at $\omega_p/2\pi = 10.15$ MHz and the optimized spectra obtained using the pulse sequence described in the text. (Reproduced by permission of Academic Press from C. Gemperle et al., *J. Magn. Reson.*, 1990, **87**, 502)

stellacyanin, are shown recorded for two different values of the spin echo delay time τ in the detection period. The values of τ used in the detection period are indicated on the echo envelope waveform shown in the inset. These coherence effects can have important consequences for the analysis of the ENDOR spectrum. Note that the relative amplitudes of the ENDOR intensities depend on the value of τ in the detection period. This effect can be used as a spectral editing technique.^{38,37}

3.1.5 Electron–Nucleus–Nucleus Triple Resonance

The Double ENDOR was originally introduced as a CW ENDOR technique to establish the connectivity of hyperfine sublevels and to determine the relative signs of the hyperfine interaction for nonequivalent nuclei.^{63,64} The pulsed implementation of the Double ENDOR experiment is shown in Figure 14.⁴¹ The experiment is analogous to the Davies ENDOR experiment, except that a second rf π pulse is inserted in the mixing period to irradiate a preselected ENDOR transition. The Double ENDOR difference spectrum, obtained from the difference between the ENDOR and Double ENDOR spectrum, identifies any changes in intensities of the ENDOR transitions induced by pumping at the second rf frequency. A peak in the Double ENDOR difference spectrum will only be

Figure 13 Davies ENDOR spectra of stellacyanin at the two pulse modulation minimum at $\tau = 0.40 \mu\text{s}$ (a) and at the maximum at $\tau = 0.51 \mu\text{s}$ (b). observed if the two sublevels each have a level in common with the ESR transition.

An example of the pulsed Double ENDOR and Double ENDOR difference spectrum recorded for the radical in the conjugated conducting polymer, polyacetylene, is shown in Figure 15.⁴¹ The Double ENDOR difference spectra indicate that the unpaired electron is coupled to protons with both positive and negative hyperfine interactions. In this case, similar conclusions were obtained using the CW Double ENDOR experiment and the results were used to determine an electron–electron correlation energy using a Hartree–Fock molecular orbital calculation.⁶⁵ However, the CW Double ENDOR experiment was only successful over a restricted temperature range, which is not the case for the pulsed version of the experiment. The pulsed Double ENDOR experiment has also been applied to studies of the irradiated malonic acid radical molecule^{45, 43} and to studies of the coordination

structure of transition metal ions and metal clusters in metalloenzymes.³⁸

3.1.6 Electron–Nucleus–Electron Triple Resonance

Another variation of a pulsed triple resonance experiment is shown in Figure 16.^{38, 37} This experiment is related to the Davies ENDOR experiment, except that the frequency of the detection pulses are offset by a frequency Δ from the frequency of the preparation pulse. This is shown schematically in Figure 17 by the magnetic positions at which the preparation, indicated by B_p , and detection, indicated by B_d , irradiation pulses are applied within the ESR absorption envelope. Sublevel polarization transfer that connects the positions B_p and B_d must originate from rf driven sublevel NMR transitions. Polarization transfer by mechanisms other than rf driven nuclear spin flips, such as by spin diffusion, are ineffective because of the short time interval between the preparation and detection period. The value of Δ therefore preselects nuclei with the hyperfine coupling $A = \Delta$. For this reason, the ENDOR spectrum generated for $\Delta = A$ is referred to as a hyperfine selective (HS) ENDOR spectrum. An HS ENDOR spectrum can also be generated by jumping the applied magnetic field.⁴²

The HS ENDOR technique is illustrated in Figure 18. The Davies ENDOR spectra for the blue copper protein, stellacyanin, recorded for the native pH 7 form of the protein and for the high-pH (pH 11) perturbed blue form of the protein are shown in Figures 18(a) and 18(b), respectively. The spectra are identical except for the intensity of a transition at 21 MHz observed in the spectrum of the high-pH form. The assignment of this peak is facilitated using the HS ENDOR experiment, as

Figure 16 Pulsed electron–nucleus–electron triple resonance pulse sequence. (Reproduced by permission of Academic Press from H. Thomann and M. Bernardo, in ‘Methods in Enzymology’, eds. J. F. Riordan and B. L. Vallee, London 1993, Vol. 227, Chap. 6)

illustrated by the three HS ENDOR spectra recorded for values of $\Delta = 19$, 42, and 36 MHz, which are shown in Figures 18(c), 18(d) and 18(e) respectively.

3.2 EPR Detected Sublevel Nuclear Coherence

Sublevel coherence can be created by a $\pi/2$ rf pulse applied at the end of the preparation period. Once created, this sublevel coherence can be manipulated in analogy to many other solid state NMR experiments. Specific examples of these type of experiments are described in this section.

3.2.1 Nuclear Free Induction

The evolution of the sublevel coherence under free precession in the local field can be detected indirectly using the pulse sequence shown in Figure 19.^{41,43} The frequency of the rf pulses are set to excite a transition in the ENDOR spectrum. The sublevel coherence evolving during the evolution time t_1 is converted back to electron spin longitudinal polarization by a second rf $\pi/2$ pulse. The sublevel coherence signal at evolution time t_1 is then detected indirectly from the intensity

Figure 18 Davies ENDOR spectra of the native (pH 7) form (a) and the high-pH (pH 11) form (b) of stellacyanin. HS ENDOR spectra of the high pH form with $\Delta = 19.0$ (c), 42.0 (d), and 36 (e) MHz were used to assign the feature at 21 MHz to nitrogen. (Reproduced by permission of Academic Press from H. Thomann and M. Bernardo, in ‘Methods in Enzymology’, eds. J. F. Riordan and B. L. Vallee, London, 1993, Vol. 227, Chap. 6)

modulation of the primary electron spin echo in the detection period. The sublevel free induction signal is then detected point by point by incrementing t_1 on successive pulse sequence iterations. Both the in-phase and phase-quadrature sublevel free precession signals can be detected by phase shifting the relative phase of the two rf pulses by $\pi/2$. Additional phase cycling by π can be used to cancel the effects of electron spin–lattice magnetization recovery during the t_1 evolution period. The rf pulse excitation bandwidth is usually much smaller than the spectral spread of the ENDOR spectrum. In order to record the entire ENDOR spectrum, the pulse sequence shown in Figure 19 must be repeated with the rf frequency incremented on successive experiments. A spectral slice of the overall ENDOR spectrum, determined by the bandwidth of the rf excitation pulse, is recorded for each selected rf. The whole ENDOR spectrum is reconstructed by adding the slices of the limited spectral regions recorded in each experiment.

The ESR detected sublevel free precession experiment is illustrated in Figure 20. These data are collected for a crystal of irradiated malonic acid. In the Davies ENDOR spectrum, a transition that shows no evidence of fine structure is observed at 14.42 MHz. The in-phase and phase-quadrature sublevel free precession signals recorded using the pulse sequence in Figure 19 and the procedure described above are shown in Figure 20(a). The complex Fourier transform of these waveforms is shown in Figure 20(b). This spectrum indicates that the ENDOR line is composed of three overlapping

Sanada, Washington, DC, 1993, Chap. 4)

transitions which are not resolved in the Davies ENDOR spectrum.

3.2.2 Multiple Quantum Electron–Nucleus Coherence

The coupling of two or more nuclei with equivalent hyperfine couplings can be detected indirectly using the pulse sequences shown in Figure 21.^{41,66} The sublevel polarization can be created using either the inversion–recovery technique with primary spin echo detection (i.e. as in the Davies ENDOR pulse sequence) or by the two pulse excitation in the preparation period with a single pulse in the detection

Figure 21 Multiple quantum (MQ) ENDOR pulse sequences: Davies MQ ENDOR (a) and Mims MQ ENDOR (b). (Reproduced by permission of Laser Pages Publishing from H. Thomann and M. Bernardo, *Isr. J. Chem.*, 1992, **32**, 323)

period to create a stimulated echo (i.e. as in the Mims ENDOR pulse sequence). An n -quantum sublevel coherence is detected using the phase incrementation technique in analogy to the NMR experiment.^{53,67} An n -quantum coherence accumulates a phase $\theta_n = n\omega_{\text{ENDOR}}t_{\text{evol}}$ where t_{evol} is an evolution time and ω_{ENDOR} is the sublevel transition frequency.

In the present experiments the phase accumulation occurs during the nutation of the sublevel polarization so that $t_{\text{evol}} = t_{\text{p}}^{\text{rf}}$. This phase accumulation can be detected by incrementing the phase of the rf mixing pulse in the middle of the mixing period. Theoretically, the optimum ENDOR signal is obtained by applying two $\pi/2$ rf pulses. Each point on the plot of the phase interferogram is collected by incrementing the phase of the second rf pulse on successive pulse sequence iterations.

An example of a multiple quantum spectrum recorded using the pulse sequence in Figure 21(a) for the malonic acid radical molecule is shown in Figure 22.⁶⁶ Multiple quantum coherences up to $n = 3$ are observed for an ENDOR transition at 14.42 MHz recorded for the malonic acid radical molecule in a crystal at an arbitrary orientation. This is consistent with the three lines observed in the ESR detected sublevel FID spectra recorded under identical conditions [Figure 20(b)]. Multiple quantum spectra recorded for several evolution times for free precession are also shown in Figure 22. The oscillation for each order of coherence originates from the free precession of transverse sublevel magnetization in the presence of the local field.

3.2.3 Nuclear Spin Echoes

Hyperfine sublevel spin echoes can be created and detected indirectly by inserting a refocusing rf pulse in the evolution period of the mixing period for the pulse sequence shown in Figure 20. The pulse sequence for this indirect detection of sublevel spin echoes is shown in Figure 23.^{40,41} The first rf pulse in the mixing period creates sublevel coherence. This coherence evolves under free precession for time τ_n and is

Figure 22 Davies multiple quantum ENDOR spectra of the malonic acid radical for various evolution times. (Reproduced by permission of Laser Pages Publishing from H. Thomann and M. Bernardo, *Isr. J. Chem.*, 1992, **32**, 323)

Figure 23 Pulse sequence for EPR detection of sublevel spin echo. (Reproduced by permission of the American Chemical Society from H. Thomann and M. Bernardo, in 'Advances in Chemistry Series 229: Magnetic Resonance of Carbonaceous Solids', eds. R. E. Botto and Y. Sanada, Washington, DC, 1993, Chap. 4)

then refocused by the rf π pulse. The sublevel spin echo formed at time τ_n after the refocusing pulse can be detected by incrementing the time t_1 of the third rf mixing pulse. The third rf pulse transforms the sublevel coherence into two spin electron–nucleus longitudinal order. This is transformed to electron spin coherence for detection of the electron spin polarization by the microwave pulses in the detection period.

The sublevel echo can be detected point by point by incrementing the value of t_1 from $t_1 < \tau_n$ to $t_1 > \tau_n$ on successive pulse sequence iterations. In each pulse sequence iteration the sublevel coherence is detected by the change in intensity of the electron spin echo in the detection period. An example of sublevel spin echoes detected by this procedure for an X-ray irradiated malonic acid crystal are shown in the inset of Figure 24. The two sublevel spin echoes shown were recorded for τ_n values of 5 and 20 μ s.

The circles shown in the inset of Figure 24 indicate the echo envelope intensities recorded for several values of $t_1 = \tau_n$. The full sublevel spin echo decay envelope along with a fit to a single exponential and the residuals for the fit are also shown in Figure 24. These sublevel echoes and envelope decay were recorded for the $\nu_+ = 30.19$ MHz ENDOR transition. This corresponds to the proton NMR transition for the α proton of the $\cdot\text{CH}(\text{COOH})_2$ radical molecule which is shifted to the high-frequency side of the proton Larmor frequency. The sublevel T_{2n} decay time obtained from the single exponential fit shown

Figure 24 The sublevel spin echo decay recorded with $t_1 = \tau_n$ along with the fit to a single exponential and the residuals of the fit. (Reproduced by permission of the American Chemical Society from H. Thomann and M. Bernardo, in 'Advances in Chemistry Series 229: Magnetic Resonance of Carbonaceous Solids', eds. R. E. Botto and Y. Sanada, Washington, DC, 1993, Chap. 4)

in Figure 24 is 60 μ s. The proton T_{2n} values measured for $\nu_{\text{rf}} = \nu_n$ are shorter than the values measured at frequencies shifted away from the proton Larmor frequency.

Similar results have been obtained in sublevel nuclear T_{2n} studies of protons in coal samples.⁴⁶ In these coal studies, the ESR detected sublevel T_{2n} values measured at $\nu_{\text{rf}} = \nu_n$ were similar to the value measured directly by NMR.⁶⁸ The ESR detected sublevel T_{2n} values increased for NMR transitions shifted further away from the proton Larmor frequency. Apparently the time-dependent local magnetic field from the hyperfine interaction is not an effective sublevel T_{2n} relaxation mechanism. The T_{2n} value measured directly by NMR is determined by the proton homonuclear dipolar coupling. The equivalence of the value measured in the ESR detected sublevel T_{2n} experiment for $\nu_{\text{rf}} = \nu_n$ suggests that the T_{2n} value is also determined by the proton dipolar interaction with the hyperfine coupling serving only as a mechanism for detecting the sublevel coherence signal. Quite different results can be expected if the time dependence of the local field is an effective T_{2n} mechanism. In this case the T_{2n} values would be expected to decrease as the NMR transition frequency is shifted away from the proton Larmor frequency.

3.3 Coherence Transfer ENDOR

In analogy to the coherence transfer experiments known in NMR spectroscopy, it is also possible to detect the hyperfine sublevel transitions by an electron–nuclear double resonance coherence transfer experiment.^{41,43,69} Three different pulse sequences for coherence transfer ENDOR experiments are shown in Figure 25. The basic principle in all three types of experiment is similar. The rf pulses applied during the period of free precession of the electron spin coherence created by a $\pi/2$ microwave pulse interfere with the refocusing of this electron coherence following the microwave π pulse.

Figure 25 Pulse sequences for coherence transfer ENDOR

This occurs if the rf pulse is on resonance with an NMR transition that has a sublevel in common with the electron spin eigenlevel that belongs to the states from which the electron spin coherence was created. In this case, the sublevel NMR transition shifts the phase of the electron spin coherence which is detected as an attenuation of the electron spin echo. If the rf pulse is a π pulse the electron spin echo intensity is reduced to zero resulting in $\Delta\chi_e/\chi_e = 1$. If the rf pulse is a 2π pulse, the echo intensity changes sign resulting in $\Delta\chi_e/\chi_e = 2$. If a 4π pulse is applied, the electron spin echo intensity returns to its original intensity. This response of the electron spin echo intensity to the rotational symmetry of the sublevel nutation angle is called the ‘spinor property’ and is a property of wavefunctions for spin- $\frac{1}{2}$ particles.

The ENDOR spectrum recorded using the pulse sequence shown in Figure 25(a) is sufficient to observe the coherence transfer ENDOR effect. However, the application of a single rf pulse also produces a large Bloch–Siegert (BS) frequency shift $\omega_{BS} = -\gamma_e(B_2^2/B_0)$, which results in a phase shift of $\omega_{BS}t_p^{rf}$. Since the rf magnetic field strength is not constant as a function of frequency across the ENDOR spectrum, the Bloch–Siegert phase shift is observed as a broad feature, as shown in Figure 26(a), which can mask the ENDOR transitions. The Bloch–Siegert phase shift can be refocused by applying a second rf pulse, as shown in Figure 25(b), which is symmetrically displaced about the microwave refocusing pulse. This eliminates the broad feature in the ENDOR spectrum as shown in Figure 26(b). The maximum ENDOR effect of $\Delta\chi_e/\chi_e = 1$ is observed when the two rf pulses are π pulses. The efficiency of the ENDOR effect can theoretically be increased to $\Delta\chi_e/\chi_e = 2$ if the two rf pulses are 2π pulses but with a 90° shift introduced, as shown in Figure 25(c).^{41,43} The enhancement in the ENDOR signal intensity is shown in Figure 26(c). In practice, the ENDOR efficiency is improved for this phase shifted spinor ENDOR pulse sequence, but because of technical limitations (primarily pulse imperfections) the increase in efficiency is much smaller than theoretically expected. Another limitation of coherence transfer ENDOR experiments is that the ENDOR lines are usually power broadened because of the short electron phase memory time encountered for most samples. It is rare that phase memory times are longer than a few microseconds, even at liquid

Figure 26 Coherence transfer single crystal ENDOR spectra of the malonic acid radical recorded with corresponding pulse sequences shown in Figure 25. (Reproduced by permission of the American Chemical Society from C. Gemperle and A. Schweiger, *Chem. Rev.*, 1991, **91**, 1481)

helium temperatures. Nevertheless, the coherence transfer ENDOR experiment has revealed fundamentally interesting properties of the spin dynamics of the electron–nucleus spin system.

4 CONCLUDING REMARKS

ENDOR and the extension to PE NMR spectroscopy are presently tools of the specialist. They are very powerful techniques in specific cases where the spectra and/or spin dynamics for the nuclei of interest are strongly influenced by the large local magnetic fields originating from the hyperfine coupling with unpaired electron spins. In such cases the NMR transition frequencies are shifted by very large values when compared with NMR spectra of diamagnetic samples. When these circumstances do apply, ENDOR and PE NMR spectroscopy are often the only techniques which can provide the desired information. In this review we have included examples of applications in organic solids, metallobiochemistry, and organometallic chemistry. With the introduction of pulsed excitation techniques, extension to multiple irradiation frequencies, and the introduction of commercially available pulsed instrumentation, continued development of the methodology and an increasing range of applications can be expected for these techniques in the near future. Recent developments in high-frequency ESR,⁷⁰ including the extension to high-frequency ENDOR,⁷¹ will also likely expand the range of research applications. The combination of pulsed ESR and pulsed NMR should continue to be a vibrant area of research as new technology becomes available and as new methodologies and applications are developed.

1 INTRODUCTION

This article is devoted to Floquet theory and its applications to NMR spectroscopy. The formalism presented here is based on that introduced by Shirley¹ in 1965 for describing the interaction between an oscillating field and a quantum system. This theory provides a solution of the Liouville–von Neumann equation for the spin density operator $\hat{\rho}(t)$ of a system that experiences a periodically time-dependent spin Hamiltonian $\hat{\mathcal{H}}(t)$. In NMR this Hamiltonian can be the spin Hamiltonian of a spin system rotating in the magnetic field, or a Hamiltonian that describes a time-dependent rf spin excitation scheme. The need to obtain accurate solutions for the density operator is essential in NMR spectroscopy, because during NMR experiments, one monitors the time evolution of a set of spin coherences (i.e., superposition states) of a system either sequentially or simultaneously. The calculations necessary to solve the Liouville–von Neumann equation for the density operator,^{2,3}

$$\frac{d}{dt}\hat{\rho}(t) = i[\hat{\rho}(t), \hat{\mathcal{H}}(t)] \quad (1)$$

can become very complicated. A variety of theoretical approaches can be exploited^{2–10} for dealing with this equation for the description of NMR experiments.

One of the widely used approaches for the evaluation of $\hat{\rho}(t)$, at constant time intervals, is the average Hamiltonian theory (AHT).^{5,11} This theory provides the methodology to evaluate a time-independent average Hamiltonian that governs the effective time dependence of $\hat{\rho}(t)$ at the end of these intervals. The actual evaluation of this average Hamiltonian is performed by calculating successive terms of a Magnus expansion.¹² The AHT has been used especially for the construction of average Hamiltonians that describe multiple pulse experiments,^{3–8,13} and for the design of selective excitation and decoupling schemes.^{14,15} For a detailed discussion of AHT, see *Average Hamiltonian Theory*.

An additional approach that offers a way to solve the equation of motion of the density operator, with a periodically time-dependent Hamiltonian, can be found in the form of Floquet theory.^{1,4,16} Maricq¹⁷ has discussed the utilization of this theory and has made a comparative study of AHT and the Floquet approach. This approach provides the tools to evaluate effective Hamiltonians following an expansion procedure. An additional comparison between the two theories

has been presented by Llor,¹⁸ showing that the two theories are equivalent when the Floquet Hamiltonians are expanded with the help of the Van Vleck transformation.¹⁹ Goldman et al.¹⁰ have shown how Floquet theory can be exploited in terms of a perturbation expansion, based on operator commutators, for evaluating effective Hamiltonians.

The Floquet formalism, as discussed in this article, does not make use of these expansion methods for the calculation of effective Hamiltonians. However, it does provide a basic methodology for solving the Liouville–von Neumann equation at all times. Wherever necessary, approximation or numerical methods are applied to estimate the solutions. Our Floquet approach follows the dressed states^{17,18,20,21} viewpoint, and is a straightforward extension of Shirley’s theory.¹ It can be considered as a semiclassical analog of the dressed state quantum description of a system in an electromagnetic field.^{1,20,21}

A variety of applications of the Floquet theory for magnetic resonance problems can be found in the literature. Freed et al.²² used it for calculating saturation effects in ESR spectra. N -photon pulses²³ as well as broadband and narrowband excitation schemes²⁴ have been designed using this theory. Goelman et al.²⁵ explained in terms of this formalism the appearance of nonlinear irradiation fields in multiband adiabatic inversion pulses. In MAS NMR spectroscopy, the Floquet approach has been exploited to explain a variety of spectroscopic effects.^{26–29} Using perturbation theory, McDowell et al.²⁸ applied the Floquet formalism to describe experiments on homonuclear spin pairs, and Augustine et al.²⁹ used it for calculating field-dependent second-order dipolar shifts in MAS NMR. Rotational resonance has been explained in terms of degeneracies of the Floquet state,³⁰ and effective Hamiltonians have been derived for dipolar recoupling experiments.^{31,32} An extension of the theory was also utilized by Schmidt et al.³³ and by Luz et al.³⁴ in calculations of dynamic MAS spectra.

The rest of this article is divided into three sections. First, the basic Floquet theory is introduced in a general way, without giving examples; secondly, stroboscopic detection of spin parameters is discussed; finally, some examples of the use of this theory are given. The last example deals with the extension of the theory for describing dynamic MAS spectra. The discussions in this article do not deal with large multispin systems. Thus, multiple spin diffusion and spin temperature concepts will not be discussed here. An effort has been made to introduce basic concepts, derive the essential equations, and to present the methodologies of the Floquet theory for application in NMR. The derivations of a large part of the equations are self-contained.

In the modern era of computers, the equation of motion of the density matrix can be solved numerically for a wide variety of problems. Thus, to simulate spectra or to predict and explain spin responses, it no longer always seems necessary to use a ‘theory’. However, these theories provide physical insights and ways of thinking about problems. With this in mind, it is appropriate to discuss Floquet theory in this Encyclopedia. Although the representation of the theory might sometimes look cumbersome and the mathematical derivations rather lengthy, the Floquet formalism has enabled a better understanding of a variety of NMR results, created different and stimulating insights into spectroscopic phenomena, and helped to generate new experimental approaches.

2 THE FLOQUET FORMALISM

2.1 The Schrödinger Equation

In this section, the Floquet Hamiltonian of a spin system, experiencing a periodically time-dependent spin Hamiltonian $\hat{\mathcal{H}}(t)$, is introduced, and the expression for the matrix elements of its spin evolution operator is derived. The solution of the Liouville–von Neumann equation for the spin density operator $\hat{\rho}(t)$ of such a system can be obtained by evaluating the unitary spin evolution operator^{3–8}

$$\hat{U}(t) = T \exp \left[-i \int_0^t \hat{\mathcal{H}}(t') dt' \right] \quad (2)$$

and by inserting the initial state of the density operator $\hat{\rho}(0)$ at $t = 0$ in the solution of equation (1):

$$\hat{\rho}(t) = \hat{U}(t) \hat{\rho}(0) \hat{U}^{-1}(t) \quad (3)$$

T is the Dyson time-ordering operator.

Any evolution operator can be expressed in terms of a unitary operator $\hat{F}(t)$, ensuring that $\hat{U}(0) = 1$ and satisfying the Schrödinger equation:^{35,36}

$$\frac{d}{dt} \hat{F}(t) = -i \hat{\mathcal{H}}(t) \hat{F}(t) \quad (4)$$

with

$$\hat{U}(t) = \hat{F}(t) \hat{F}^{-1}(0) \quad (5)$$

When the Hamiltonian and the evolution operator are represented in a manifold of spin states $\{|p\rangle, |q\rangle, |r\rangle \dots\}$, equation (4) will take the form of a set of coupled homogeneous differential equations for the elements $\langle p | \hat{F}(t) | q \rangle$ and with coefficients $\langle p | \hat{\mathcal{H}}(t) | q \rangle$. The generalized form of the solution of such a set of coupled equations, with periodically time-dependent coefficients, was derived by Floquet.³⁷

When the time period of the Hamiltonian is T , and its fundamental frequency $\omega = 2\pi/T$, its matrix elements can be expanded as

$$\langle p | \hat{\mathcal{H}}(t) | q \rangle = \sum_{n=-\infty}^{\infty} \langle p | \hat{h}^n | q \rangle \exp(in\omega t) \quad (6)$$

and the solutions for the matrix elements of $\hat{F}(t)$ are, according to Floquet^{1,16} of the form

$$\langle p | \hat{F}(t) | q \rangle = \sum_{n=-\infty}^{\infty} \langle p | \hat{f}_n | q \rangle \exp(-i\lambda_0^q t) \exp(in\omega t) \quad (7)$$

Thus, these matrix elements can be expressed as products of the elements of a periodically time-dependent matrix, $\langle p | \sum_n \hat{f}_n \exp(in\omega t) | q \rangle$, and an exponent, $\exp(-i\lambda_0^q t)$. The dimension of the periodically time-dependent matrix is equal to the dimension of the matrix representation of $\hat{F}(t)$, and the number of λ_0^q parameters is equal to this dimension as well. Insertion of equations (6) and (7) into equation (4) yields a set

of equations for the Fourier coefficients of the matrix elements of $\hat{F}(t)$:

$$\sum_r \sum_{m=-\infty}^{\infty} (\langle p | \hat{h}^{n-m} | r \rangle + n\omega \delta_{nm} \delta_{pr}) \langle r | \hat{f}_m | q \rangle = \lambda_0^q \langle p | \hat{f}_n | q \rangle \quad (8)$$

2.2 The Floquet Hamiltonian

The set of coupled equations in equation (8) has the form of an eigenvalue–eigenvector equation. Shirley¹ suggested rewriting this set by defining a Hermitian Floquet Hamiltonian $\hat{\mathcal{H}}_F$ of infinite dimension, represented in the manifold of dressed spin states $\{|pn\rangle\}$, with the Fourier mode indices $n = -\infty, \dots, \infty$:

$$\langle pn | \hat{\mathcal{H}}_F | qm \rangle = \langle p | \hat{h}^{n-m} | q \rangle + n\omega \delta_{nm} \delta_{pq} \quad (9)$$

The general form of the matrix representation of the Floquet Hamiltonian is shown in Figure 1. The elements of $\hat{\mathcal{H}}_F$ are time-independent and satisfy an eigenvalue–eigenvector equation of the form

$$\sum_r \sum_{m=-\infty}^{\infty} \langle pn | \hat{\mathcal{H}}_F | rm \rangle \langle rm | \lambda_k^q \rangle = \lambda_k^q \langle pn | \lambda_k^q \rangle \quad (10)$$

Comparing this equation with equation (8) reveals that the eigenvalues of $\hat{\mathcal{H}}_F$ are equal to

$$\lambda_k^q = \lambda_0^q + k\omega \quad (11)$$

and that the elements of the eigenvectors of $\hat{\mathcal{H}}_F$ are equal to

$$\langle pn | \lambda_k^q \rangle = \langle pn - k | \lambda_0^q \rangle = \langle p | \hat{f}_{n-k} | q \rangle \quad (12)$$

Because $\hat{\mathcal{H}}_F$ is of infinite dimension and its eigenvalues satisfy equation (11), the values of the principal eigenvalues λ_0^q are not uniquely determined.^{1,16–18} It is always possible, however, to choose $-0.5\omega < \lambda_0^q \leq 0.5\omega$ and to adjust the n indices in the eigenvector elements accordingly.

In Figure 2 the comparison between equations (8) and (9) is demonstrated schematically. Using the definitions for the parameters λ_0^q and the elements of $\hat{f}_n$ in the expression for matrix elements of $\hat{F}(t)$ in equation (7), the evolution operator becomes

$$\begin{aligned} \langle p | \hat{U}(t) | q \rangle &= \sum_r \langle p | \hat{F}(t) \hat{F}^{-1}(0) | q \rangle \\ &= \sum_r \sum_{n,m=-\infty}^{\infty} \langle pn | \lambda_0^r \rangle \exp(-i\lambda_0^r t) \langle \lambda_0^r | qm \rangle \exp(in\omega t) \\ &= \sum_r \sum_{n,m=-\infty}^{\infty} \langle pn - m | \lambda_{-m}^r \rangle \\ &\quad \times \exp(-i\lambda_{-m}^r t - im\omega t) \langle \lambda_{-m}^r | q0 \rangle \exp(in\omega t) \end{aligned} \quad (13a)$$

Figure 1 A schematic representation of the infinite p - q blocks of a Floquet matrix

$$\hat{\mathcal{H}}^F = \sum_{p < q} \sum_{n=-\infty, n \neq 0}^{\infty} \omega \hat{N}^{pp} + 2z_n^{pp} \hat{Z}_n^{pp} + 2x_n^{pq} \hat{X}_n^{pq} + 2y_n^{pq} \hat{Y}_n^{pq}$$

with elements $\langle pn|\hat{\mathcal{H}}_F|pm\rangle = z_{n-m}^{pp} + \omega\delta_{nm}$, $\langle pn|\hat{\mathcal{H}}_F|qm\rangle = x_{n-m}^{pq} - iy_{n-m}^{pq} = p_{n-m}^{pq}$ and $\langle qn|\hat{\mathcal{H}}_F|pm\rangle = x_{n-m}^{pq} + iy_{n-m}^{pq} = m_{n-m}^{pq}$ and $p_n^{pq} = m_{-n}^{pq*}$

which results in

$$\langle p|\hat{U}(t)|q\rangle = \sum_{n=-\infty}^{\infty} \langle pn|\exp(-i\hat{\mathcal{H}}_F t)|q0\rangle \exp(in\omega t) \quad (13b)$$

In this derivation, we have used $\sum_{r,m} \langle pn|\lambda_{-m}^r\rangle \lambda_{-m}^r \langle \lambda_{-m}^r|q0\rangle = \langle pn|\hat{\mathcal{H}}_F|q0\rangle$ and replaced $n - m$ by n .

The dependence of the matrix elements of the spin evolution operator on the Floquet Hamiltonian in equation (13b) forms the basic equation of Shirley's Floquet formalism.¹ It demonstrates that the Floquet Hamiltonian governs the evolution of the spin system and suggests that this time-independent Hamiltonian can be utilized to derive the exact time dependences of coherences and polarizations of this system.

The time-independent Floquet Hamiltonian $\hat{\mathcal{H}}_F$ replaces the periodically time-dependent Hamiltonian $\hat{\mathcal{H}}(t)$ (see Figure 1).

For each $N \times N$ matrix representation of $\hat{\mathcal{H}}(t)$, a Floquet Hamiltonian matrix can be derived by a Fourier transformation of all matrix elements of $\hat{\mathcal{H}}(t)$ and by an insertion of the Fourier coefficients in equation (9). Thus, $\hat{\mathcal{H}}_F$ consists of $N \times N$ infinite matrix blocks and has a special diagonal band structure as shown in Figure 1.

The Floquet matrices can in principle be diagonalized as

$$\hat{\mathcal{H}}_F = \hat{D}_F \hat{\Lambda}_F \hat{D}_F^{-1} \quad (14)$$

and have eigenvalues equal to $\langle qn|\hat{\Lambda}_F|qn\rangle = \lambda_n^q$ and eigenvector elements equal to $\langle pn|\hat{D}_F|qm\rangle = \langle pn|\lambda_m^q\rangle$. The number of independent parameters λ_0^q that define the eigenvalues is equal to N , and the eigenvectors satisfy equation (12). The unitary diagonalization matrix $\hat{D}_F$ is composed of these eigenvectors, and has a similar diagonal band structure to $\hat{\mathcal{H}}_F$, as shown in Figure 3.

$$\begin{array}{c}
 \begin{array}{c} (r,m) \qquad (q) \qquad (q) \\
 \left[\begin{array}{c} \langle p|\hat{H}^{n-m}|r\rangle + n\omega\delta_{nm}\delta_{pr} \end{array} \right] \left[\begin{array}{c} \langle r|\hat{f}_m|q\rangle \end{array} \right] = \left[\begin{array}{c} \langle p|\hat{f}_m|q\rangle \end{array} \right] \boxed{\lambda_0^q}
 \end{array} \\
 \\
 \begin{array}{c}
 \left[\begin{array}{c} \langle p|\hat{H}^{n-m}|r\rangle + n\omega\delta_{nm}\delta_{pr} \end{array} \right] \left[\begin{array}{c} \langle rm|\lambda_k^q \rangle \\ \vdots \\ \langle rm|\lambda_k^q \rangle \end{array} \right] = \left[\begin{array}{c} \langle pn|\lambda_k^q \rangle \\ \vdots \\ \langle pn|\lambda_k^q \rangle \end{array} \right] \left[\begin{array}{c} \lambda_2^q \\ \lambda_1^q \\ \lambda_0^q \\ \lambda_{-1}^q \\ \lambda_{-2}^q \end{array} \right]
 \end{array}
 \end{array}$$

Figure 2 A schematic representation of equation (8) and (10). The eigenvalue equation at the top corresponds to equation (8). In this matrix representation, defined by elements according to the indices (p, n) and (r, m) , the q th eigenvector has an eigenvalue $\lambda q/0$. The set of eigenvalue equations at the bottom corresponds to equation (10), and shows that in the dressed state matrix representation defined by elements between $\langle pn|$ and $|rm\rangle$, a set of eigenvectors can be created that are obtained from each other by shifting their elements up or down, and also a corresponding set of eigenvalues that are obtained by adding or subtracting $n\omega$ from λ^q_0

The computational stages for the utilization of the Floquet formalism consist of the composition of the Floquet Hamiltonian $\hat{\mathcal{H}}_F$ and the insertion of the exponent $\exp(-i\hat{\mathcal{H}}_F t)$ in the expression for the matrix elements of the spin evolution operator in equation (13b). In order to evaluate the matrix elements of this exponent it is necessary to diagonalize $\hat{\mathcal{H}}_F$.

2.3 The Floquet Evolution Operator

In order to obtain a better understanding of the utilization of the Floquet Hamiltonian and to emphasize its physical significance we can introduce a Floquet propagator and a Floquet density operator.³⁸ Thus, the analogy between these operators, the spin evolution and the spin density operators, can then help us to visualize the utilization of this theory.

Let us define a Floquet evolution operator as follows:

$$\hat{U}_F(t) \equiv \exp(-i\hat{\mathcal{H}}_F t) \quad (15)$$

This operator can be considered as the solution of an equation of motion for a Floquet density matrix $\hat{R}(t)$,

$$\frac{d}{dt} \hat{R}(t) = i[\hat{R}(t), \hat{\mathcal{H}}_F] \quad (16)$$

namely,

$$\hat{R}(t) = \hat{U}_F(t) \hat{R}(0) \hat{U}_F^{-1}(t) \quad (17)$$

The similarity between these equations and the Liouville–von Neumann equation with its solution for a spin system with a time-independent Hamiltonian is apparent. A straightforward inspection, using equation (13), reveals³⁸

$$\left. \begin{aligned} \langle p|\hat{U}(t)|q\rangle &= \sum_{n=-\infty}^{\infty} \langle pn|\hat{U}_F(t)|q0\rangle \exp(in\omega t) \\ \langle p|\hat{\rho}(t)|q\rangle &= \sum_{n=-\infty}^{\infty} \langle pn|\hat{R}(t)|q0\rangle \exp(in\omega t) \end{aligned} \right\} \quad (18)$$

with

$$\langle pn|\hat{R}(0)|qm\rangle \equiv \langle p|\hat{\rho}(0)|q\rangle \delta_{nm} \quad (19)$$

The first equation is the same as equation (13b). With these definitions and relations, we can describe the evolution of spin systems with periodically time-dependent Hamiltonians, in terms of time-independent Floquet Hamiltonians that govern density matrices and create evolution operators (Figure 4). The energy levels of these Hamiltonians are defined in Floquet space and are equal to their eigenstates. The elements

	$\mu_{-3}^{pq} \quad \mu_{-2}^{pq} \quad \mu_{-1}^{pq} \quad \mu_0^{pq} \quad \mu_1^{pq} \quad \mu_2^{pq} \quad \mu_3^{pq}$	$\delta_{-3}^{qq} \quad \delta_{-2}^{qq} \quad \delta_{-1}^{qq} \quad \delta_0^{qq} \quad \delta_1^{qq} \quad \delta_2^{qq} \quad \delta_3^{qq}$
	$\mu_{-4}^{pq} \quad \mu_{-3}^{pq} \quad \mu_{-2}^{pq} \quad \mu_{-1}^{pq} \quad \mu_0^{pq} \quad \mu_1^{pq} \quad \mu_2^{pq}$	$\delta_{-4}^{qq} \quad \delta_{-3}^{qq} \quad \delta_{-2}^{qq} \quad \delta_{-1}^{qq} \quad \delta_0^{qq} \quad \delta_1^{qq} \quad \delta_2^{qq}$
	$\mu_{-5}^{pq} \quad \mu_{-4}^{pq} \quad \mu_{-3}^{pq} \quad \mu_{-2}^{pq} \quad \mu_{-1}^{pq} \quad \mu_0^{pq} \quad \mu_1^{pq}$	$\delta_{-5}^{qq} \quad \delta_{-4}^{qq} \quad \delta_{-3}^{qq} \quad \delta_{-2}^{qq} \quad \delta_{-1}^{qq} \quad \delta_0^{qq} \quad \delta_1^{qq}$
	$\mu_{-6}^{pq} \quad \mu_{-5}^{pq} \quad \mu_{-4}^{pq} \quad \mu_{-3}^{pq} \quad \mu_{-2}^{pq} \quad \mu_{-1}^{pq} \quad \mu_0^{pq}$	$\delta_{-6}^{qq} \quad \delta_{-5}^{qq} \quad \delta_{-4}^{qq} \quad \delta_{-3}^{qq} \quad \delta_{-2}^{qq} \quad \delta_{-1}^{qq} \quad \delta_0^{qq}$

Figure 3 A schematic representation of the (pq) blocks of the diagonalization matrix $\hat{D}_F = \sum_{p < q} \sum_{n=-\infty}^{\infty} 2d_n^{pp} \hat{Z}_n^{pp} + \pi_n^{pq} \hat{P}_n^{pq} + \mu_n^{pq} \hat{M}_n^{pq}$

of $\hat{R}(t)$ contain oscillating terms with frequencies that are equal to Floquet energy differences and coefficients that are functions of the eigenvectors of $\hat{\mathcal{H}}_F$. The evaluation of the time dependence of coherences and polarizations of spin systems requires, of course, the transformation of $\hat{R}(t)$ to $\hat{\rho}(t)$, as shown in equation (18).

At this stage of the discussion, it has become evident that the Floquet description of a spin system, with a spin Hamiltonian satisfying $\hat{\mathcal{H}}(t + nT) = \hat{\mathcal{H}}(t)$, is the same as for a system that has a time-independent Hamiltonian. The price we pay for the transformation of the time-dependent Hamiltonian $\hat{\mathcal{H}}(t)$ to the time-independent Hamiltonian $\hat{\mathcal{H}}_F$ is the fact that we must deal with a multiple infinite matrix $\hat{\mathcal{H}}_F$.

2.4 Expectation Values of Observables

The expectation value of an observable $\hat{O}$ of the spin system is evaluated by³⁶

$$\langle \hat{O} \rangle = \text{tr}[\rho(t) \hat{O}] = \sum_{p,r} \langle p | \hat{\rho}(t) | r \rangle \langle r | \hat{O} | p \rangle \quad (20)$$

An expression for $\langle \hat{O} \rangle$ can also be obtained, when we use the dependence of $\hat{R}(t)$ on $\hat{\rho}(t)$, as given in equation (18):

$$\langle \hat{O} \rangle = \sum_{n=-\infty}^{\infty} \sum_p \langle pn | \hat{R}(t) \hat{O}_F | p0 \rangle \exp(in\omega t) \quad (21)$$

where the matrix elements of $\hat{O}_F$ are given by elements of a block-diagonal matrix,

$$\langle pn | \hat{O}_F | qm \rangle = \langle p | \hat{O} | q \rangle \delta_{nm} \quad (22)$$

To show that the expectation values are indeed functions of terms that oscillate with frequencies equal to the differences between Floquet eigenstates, we insert in equation (21) the solution for $\hat{R}(t)$ [equation (16)] and the expression for $\hat{\mathcal{H}}_F$, in terms of its eigenvalues and eigenvectors [below equation (13b)]. The result after a straightforward calculation yields³⁸

$$\langle \hat{O} \rangle = \sum_{n=-\infty}^{\infty} \sum_{p < q} A^{pq} \langle \lambda_n^q | \hat{O}_F | \lambda_0^p \rangle \exp[i(\lambda_n^q - \lambda_0^p)t] \quad (23)$$

Figure 4 A schematic representation of the comparison between the equation of motions of $\hat{\rho}(t)$ and $\hat{R}(t)$. The matrix elements of the spin Hamiltonian $\hat{\mathcal{H}}(t)$ are time-dependent, and the dimension of the matrix is defined by the number of independent basis functions $\{|p\rangle\}$ of the spin system. The matrix elements of the Floquet Hamiltonian $\hat{\mathcal{H}}_F$ are time-independent, but the dimension of the matrix is infinite, i.e., an infinite block matrix exists for each pair of basis functions $\{|p\rangle, |q\rangle\}$

Figure 5 Part of the Floquet energy level scheme of the eigenvectors $\{|\lambda_n^p\rangle\}$ of a Floquet matrix. Allowed transitions between eigenstates $|\lambda_n^p\rangle$ and $|\lambda_0^q\rangle$ result in oscillating terms $\exp[i(\lambda_n^p - \lambda_0^q)t]$ in the expectation values of observables O , and create frequency spectra after Fourier transformations of these time-dependent expectation values (O). When these values are multiplied by a decaying function, the Fourier transform spectrum has bands at the frequencies $\lambda_n^p - \lambda_0^q$ and amplitudes proportional to $\langle \lambda_n^p | \hat{O}_F | \lambda_0^q \rangle$

where the normalization coefficients for each group of terms with frequencies $(\lambda_n^q - \lambda_0^p) = (\lambda_0^q - \lambda_0^p) + n\omega$ are equal to

$$A^{pq} = \sum_{m=-\infty}^{\infty} \langle \lambda_0^p | \hat{R}(0) | \lambda_m^q \rangle \quad (24)$$

Thus, the expectation values monitor the differences between the eigenvalues of $\hat{\mathcal{H}}_F$ of allowed Floquet transitions. A schematic representation of this discussion is given in Figure 5.

At this stage of the discussion, a general strategy for the use of Floquet theory can be presented. After the definition of the spin system and its periodically time-dependent Hamiltonian, the following steps must be made in order to take full advantage of this approach.

1. The Floquet Hamiltonian must be constructed from the Fourier components of the periodically time-dependent spin Hamiltonian [equation (9)].
2. Then the eigenstates and eigenvalues of the Floquet Hamiltonian must be evaluated via the diagonalization of $\hat{\mathcal{H}}_F$ [equation (14)].
3. The initial value of the spin density matrix of the spin system must be transformed to $\hat{R}(0)$ and the desired observable $\hat{O}$ to $\hat{O}_F$ [equations (19) and (22)].

4. Finally, the matrix elements of $\hat{O}_F$ and $\hat{R}(0)$ between the eigenstates of the Floquet Hamiltonian must be calculated and inserted into the expression for $\langle \hat{O} \rangle$ [equations (23) and (24)].

The above procedure is only practical when we know how to diagonalize $\hat{\mathcal{H}}_F$. Thus, it is necessary to discuss the diagonalization procedures for the Floquet matrices. In many cases, perturbation theory or other approximation methods will be necessary to estimate the eigenvalues and eigenvectors of this matrix.^{1,16–19}

2.5 The Fictitious Spin-1/2 Floquet Matrices

To simplify the presentation of the infinite Floquet matrices, a set of basis matrices, in the manifold of dressed spin states $\{|pn\rangle, |qm\rangle, \dots\}$, can be introduced.^{32,38} These matrices resemble the fictitious spin- $\frac{1}{2}$ operators,^{39,40} and can be defined as follows:

$$\left. \begin{aligned} \langle pm | \hat{N}^{pp} | pm \rangle &= m, & \langle pm | \hat{I}^{pp} | pm \rangle &= 1 \\ \langle pm + n | \hat{Z}_n^{pp} | pm \rangle &= \langle p | I_z^{pp} | p \rangle = \frac{1}{2} \\ \langle pm + n | \hat{P}_n^{pq} | qm \rangle &= \langle p | I_+^{pq} | q \rangle = 1 \\ \langle qm + n | \hat{M}_n^{pq} | pm \rangle &= \langle q | I_-^{pq} | p \rangle = 1 \\ \langle pm + n | \hat{Z}_n^{pq} | pm \rangle &= -\langle qm + n | \hat{Z}_n^{pq} | qm \rangle \\ &= \langle p | \hat{I}_z^{pq} | q \rangle = \frac{1}{2} \\ \langle pm + n | \hat{X}_n^{pq} | qm \rangle &= \langle qm + n | \hat{X}_n^{pq} | pm \rangle \\ &= \langle p | \hat{I}_x^{pq} | q \rangle = \frac{1}{2} \\ \langle pm + n | \hat{Y}_n^{pq} | qm \rangle &= \langle qm + n | \hat{Y}_n^{pq} | pm \rangle^* \\ &= \langle p | \hat{I}_y^{pq} | q \rangle = -\frac{1}{2}i \end{aligned} \right\} \quad (25)$$

A schematic representation of these operators is shown in Figure 6

Figure 6 Representations of the Floquet matrices defined in equation (25)

As a result, the spin Hamiltonian

$$\hat{\mathcal{H}}(t) = \sum_{p < q} \sum_{n=-\infty}^{\infty} 2(\omega_{zn}^{pq} \hat{I}_z^{pq} + \omega_{xn}^{pq} \hat{I}_x^{pq} + \omega_{yn}^{pq} \hat{I}_y^{pq}) \exp(in\omega t) \quad (26)$$

generates a Floquet Hamiltonian of the form

$$\begin{aligned} \hat{\mathcal{H}}_F &= \sum_{p < q} \sum_{n=-\infty}^{\infty} (\omega \hat{N}^{pp} + 2\omega_{zn}^{pq} \hat{Z}_n^{pq} + 2\omega_{xn}^{pq} \hat{X}_n^{pq} + 2\omega_{yn}^{pq} \hat{Y}_n^{pq}) \\ &= \sum_{p < q} \sum_{n=-\infty}^{\infty} [\omega \hat{N}^{pp} + 2\omega_{zn}^{pq} (\hat{Z}_n^{pp} - \hat{Z}_n^{qq}) \\ &\quad + (\omega_{xn}^{pq} - i\omega_{yn}^{pq}) \hat{P}_n^{pq} + (\omega_{xn}^{pq} + i\omega_{yn}^{pq}) \hat{M}_n^{pq}] \end{aligned} \quad (27)$$

A similar relationship holds between $\hat{\rho}(t)$ and $\hat{R}(t)$:

$$\begin{aligned} \hat{\rho}(t) &= \sum_{p < q} \sum_{n=-\infty}^{\infty} [2r_{zn}^{pq}(t) \hat{I}_z^{pq} + 2r_{xn}^{pq}(t) \hat{I}_x^{pq} + 2r_{yn}^{pq}(t) \hat{I}_y^{pq}] \\ &\quad \times \exp(in\omega t) \end{aligned} \quad (28)$$

$$\begin{aligned} \hat{R}(t) &= \sum_{p \leq q} \sum_{n=-\infty}^{\infty} [2r_{zn}^{pq}(t) \hat{Z}_n^{pq} \\ &\quad + 2r_{xn}^{pq}(t) \hat{X}_n^{pq} + 2r_{yn}^{pq}(t) \hat{Y}_n^{pq}] \end{aligned} \quad (29)$$

The Floquet operators, as defined in equation (25), satisfy the following commutation relations:

$$\left. \begin{aligned} [\hat{N}^{pp} + \hat{N}^{qq}, \hat{X}_n^{pq}] &= n \hat{X}_n^{pq}, & [\hat{X}_n^{pq}, \hat{X}_m^{pq}] &= 0 \\ [\hat{N}^{pp} + \hat{N}^{qq}, \hat{Y}_n^{pq}] &= n \hat{Y}_n^{pq}, & [\hat{Y}_n^{pq}, \hat{Y}_m^{pq}] &= 0 \\ [\hat{N}^{pp} + \hat{N}^{qq}, \hat{Z}_n^{pq}] &= n \hat{Z}_n^{pq}, & [\hat{Z}_n^{pq}, \hat{Z}_m^{pq}] &= 0 \\ [\hat{N}^{pp}, \hat{Z}_n^{pp}] &= n \hat{Z}_n^{pp}, & [\hat{Y}_n^{pq}, \hat{Z}_m^{pq}] &= i \hat{X}_{n+m}^{pq} \\ [\hat{X}_n^{pq}, \hat{Y}_m^{pq}] &= i \hat{Z}_{n+m}^{pq}, & [\hat{Z}_n^{pq}, \hat{X}_m^{pq}] &= i \hat{Y}_{n+m}^{pq} \end{aligned} \right\} \quad (30)$$

These relationships can be helpful for the diagonalization of $\hat{\mathcal{H}}_F$ and the evaluation of $\hat{R}(t)$.

Up to this point we have only defined the Floquet Hamiltonian and discussed the possibility of evaluating expectation values. However, as mentioned before, the success of the application of Floquet theory depends on the success of the diagonalization of $\mathcal{H}_F$. This is nontrivial in most cases. Only some simple forms of the Floquet Hamiltonians can be diagonalized analytically. For example, the following terms can be diagonalized, because they consist of an infinite set of 2×2 matrices:

$$\left. \begin{aligned} \hat{\mathcal{H}}_F &= \omega \hat{N}^{pp} + \omega \hat{N}^{qq} + 2\omega_{zo}^{pp} \hat{Z}_0^{pp} + 2\omega_{zo}^{qq} \hat{Z}_0^{qq} \\ &\quad + 2\omega_{xn} \hat{X}_n^{pq} + 2\omega_{yn} \hat{Y}_n^{pq} \\ \hat{\Lambda}_F &= \omega \hat{N}^{pp} + \omega \hat{N}^{qq} + 2[(\omega_{xn}^{pq})^2 + (\omega_{yn}^{qq})^2] \\ &\quad + \frac{1}{4}(\omega_{zo}^{pp} - \omega_{zo}^{qq} + n\omega)^2 \hat{Z}_0^{pq} \\ &\quad + (\omega_{zo}^{pp} - n\omega) \hat{Z}_0^{pp} + (\omega_{zo}^{qq} + n\omega) \hat{Z}_0^{qq} \end{aligned} \right\} \quad (31)$$

2.6 z Diagonalization of the Floquet Hamiltonian

The diagonal blocks of the Floquet Hamiltonian can be diagonalized analytically. The purpose of this section is to show that the diagonalization of the block-diagonal Floquet Hamiltonian

$$\hat{\mathcal{H}}_F = \sum_p \left(\omega \hat{N}^{pp} + \sum_{n=-\infty}^{\infty} 2\omega_{zn}^{pp} \hat{Z}_n^{pp} \right) \quad (32)$$

results in a diagonalized Hamiltonian of the form

$$\begin{aligned} \hat{D}_F^{-1} \left[\sum_p \left(\omega \hat{N}^{pp} + \sum_{n=-\infty}^{\infty} 2\omega_{zn}^{pp} \hat{Z}_n^{pp} \right) \right] \hat{D}_F \\ = \sum_p (\omega \hat{N}^{pp} + 2\omega_{z0}^{pp} \hat{Z}_0^{pp}) \end{aligned} \quad (33)$$

and that the elements of the diagonalization matrix $d_n^{pp} = \langle pm + n | \hat{D}_F | pm \rangle$ for all m satisfy

$$\sum_{n=-\infty}^{\infty} d_n^{pp} \exp(in\omega t) = \exp \left\{ \sum_{n=-\infty, n \neq 0}^{\infty} -\frac{\omega_{zn}^{pp}}{n\omega} [\exp(in\omega t) - 1] \right\} \quad (34)$$

Thus, the eigenvalues of the block-diagonal Floquet Hamiltonian are equal to its own diagonal elements, and the elements of $\hat{D}_F$ can be obtained by a Fourier expansion, according to equation (34). In the rest of this section these results will be proven.

The Floquet Hamiltonian in equation (32) corresponds to a self-commuting diagonal spin Hamiltonian of the form

$$\hat{\mathcal{H}}(t) = \sum_p \sum_{n=-\infty}^{\infty} 2\omega_{zn}^{pp} \hat{I}_z^{pp} \exp(in\omega t) \quad (35)$$

The matrix elements of the evolution operator corresponding to this Hamiltonian can be evaluated simply by integration, $\hat{U}(t) = \exp[-i \int_0^t H(t') dt']$:

$$\begin{aligned} \langle p | \hat{U}(t) | p \rangle &= \exp(-i\omega_{z0}^{pp} t) \\ &\times \exp \left\{ - \sum_{n=-\infty, n \neq 0}^{\infty} \frac{\omega_{zn}^{pp}}{n\omega} [\exp(in\omega t) - 1] \right\} \end{aligned} \quad (36)$$

An expression for these elements can also be obtained by using the Floquet approach. Equation (33) can actually be derived first by writing the unitary $\hat{D}_F$ matrix in its most general form,

$$\hat{D}_F = \sum_p \sum_{n=-\infty}^{\infty} d_n^{pp} \hat{Z}_n^{pp}, \quad \hat{D}_F^{-1} = \sum_p \sum_{n=-\infty}^{\infty} d_{-n}^{pp*} \hat{Z}_n^{pp} \quad (37)$$

and secondly by expressing it in terms of a Hermitian diagonal block-matrix $\Sigma_p \Sigma_n \delta_n^{pp} \hat{Z}_n^{pp}$:

$$\hat{D}_F = \exp \left(i \sum_p \sum_{n=-\infty}^{\infty} \delta_n^{pp} \hat{Z}_n^{pp} \right)$$

$$\hat{D}_F^{-1} = \exp \left(-i \sum_p \sum_{n=-\infty}^{\infty} \delta_n^{pp} \hat{Z}_n^{pp} \right) \quad (38)$$

The diagonalization of $\hat{\mathcal{H}}_F$ results in the following, when we expand the transformation in its Taylor series and use the commutation relations of equations (25) and (33):

$$\begin{aligned} \hat{D}_F^{-1} \{\hat{\mathcal{H}}_F\} \hat{D}_F &= \hat{\mathcal{H}}_F - i[D_F, \hat{\mathcal{H}}_F] \\ &= \sum_p \left(\omega \hat{N}^{pp} + \sum_{n=-\infty}^{\infty} (2\omega_{zn}^{pp} + in\omega \delta_n^{pp}) \hat{Z}_n^{pp} \right) \end{aligned} \quad (39)$$

The only diagonal elements of this transformed Hamiltonian are $\sum_p 2\omega_{z0} \hat{Z}_0^{pp}$ and $\omega \hat{N}^{pp}$, which correspond to equation (33).

Thus, matrix elements of the Floquet evolution operator and the spin evolution operator can be written in terms of the elements of the diagonalization matrix $\hat{D}_F$ and the eigenvalues of $\hat{\mathcal{H}}_F$:

$$\begin{aligned} \langle pn | \hat{U}_F(t) | p0 \rangle &= \sum_{n,m=-\infty}^{\infty} \langle pn | \hat{D}_F | pm \rangle \\ &\times \exp(-i\omega_{z0}^{pp} t - im\omega t) \langle pm | \hat{D}_F^{-1} | p0 \rangle \end{aligned} \quad (40)$$

and with equations (13a) and (13b)

$$\begin{aligned} \langle p | \hat{U}(t) | p \rangle &= \sum_{n,m=-\infty}^{\infty} d_{n-m}^{pp} \exp(-i\omega_{z0}^{pp} t - im\omega t) d_{-m}^{pp*} \exp(in\omega t) \\ &= \exp(-i\omega_{z0}^{pp} t) \left[\sum_{m=-\infty}^{\infty} d_{-m}^{pp*} \right] \sum_{n=-\infty}^{\infty} d_n^{pp} \exp(in\omega t) \end{aligned} \quad (41)$$

A comparison between this result and the result in equation (36) yields the expression in equation (34).⁴¹ For each value of p the sum of all d_n^{pp} coefficients can be made equal to one. This can be derived from the fact that $\hat{U}(0) = 1$ and equation (41)

$$\sum_{n=-\infty}^{\infty} d_n^{pp} = 1 \quad (42)$$

This normalization condition for the $\{d_n^{pp}\}$ elements of the columns of the unitary matrix $\hat{D}_F$ keeps the values of the magnitudes of these elements smaller than one. When $\{\omega_{zn}^{pp}\} \ll \omega$, we get $d_0^{pp} \approx 1$ and $d_n^{pp} \approx 0$ for $n \neq 0$ and, by a Taylor expansion of equation (34), when $\{\omega_{zn}^{pp}\} < \omega$, we get $d_0^{pp} \approx 1 - \sum_n \omega_{zn}^{pp} (n\omega)^{-1}$ and $d_n^{pp} \approx \omega_{zn}^{pp} (n\omega)^{-1}$.

The Fourier expansion in equation (34) for the elements $d_n^{pp}(+)$ of the diagonalization matrix $\hat{D}_F(+)$ of a Floquet Hamiltonian with elements $\{\omega_{zn}^{pp}\}$ is the complex conjugate of the expansion for the elements $d_n^{pp}(-)$ of the diagonalization matrix $\hat{D}_F(-)$ of a Floquet Hamiltonian with elements $\{-\omega_{zn}^{pp}\}$. This follows from the facts that $d_{-n}^{pp*}(-) = d_n^{pp}(+)$ and $\langle pn + m | \hat{D}_F(+) | pm \rangle = \langle pn + m | \hat{D}_F(-) | pm \rangle$.

The elements of the diagonalization matrix of the Floquet matrix in equation (35) can also be expressed in terms of Bessel functions:³⁰

$$d_n^{pp} = \sum_{\substack{k_1, k_2, \dots, k_n = -\infty \\ k_1 + k_2 + \dots + k_n = n}}^{\infty} J_{k_1} \left(-\frac{|\omega_z^{pp}|}{2\omega} \right) J_{k_2} \left(-\frac{|\omega_z^{pp}|}{4\omega} \right) J_{k_3} \left(-\frac{|\omega_z^{pp}|}{6\omega} \right) \dots \\ \times \exp[i(k_1\phi_1 + k_2\phi_2 + k_3\phi_3 \dots)] \quad (43)$$

with $\omega_{zn}^{pp} = |\omega_z^{pp}| \exp(i\phi_n)$.

2.7 Numerical Diagonalization and Perturbation Theory

The diagonalization of the Floquet Hamiltonian is in many instances only possible via numerical calculations. These calculations require a truncation of the infinite matrix. The block size N of the truncated Hamiltonian can be chosen according to the magnitude of the off-diagonal elements and the convergence of the eigenvalues for increasing matrix dimension. For large off-diagonal elements or for elements that are far off-diagonal, it is sometimes recommended to define the truncated matrix in the manifold of Floquet states in the order $\{|pN\rangle|qN\rangle|rN\rangle\}\{|pN-1\rangle|qN-1\rangle|rN-1\rangle\}\dots\{|p0\rangle|q0\rangle|r0\rangle\}\dots\{|p-N+1\rangle|q-N+1\rangle|r-N+1\rangle\}\{|p-N\rangle|q-N\rangle|r-N\rangle\}$ rather than in the order $\{|pN\rangle|pN-1\rangle\dots|p0\rangle\dots|p-N+1\rangle|p-N\rangle\}\{|qN\rangle|qN-1\rangle\dots|q0\rangle\dots|q-N+1\rangle|q-N\rangle\}\{|rN\rangle|rN-1\rangle\dots|r0\rangle\dots|r-N+1\rangle|r-N\rangle\}$, when standard diagonalization subroutines are used in computer calculation.

Figure 7 A schematic representation of the degenerate perturbation theory treatment of part of a Floquet matrix $\hat{\mathcal{H}}_F$ that has degenerate diagonal elements, with values $\langle pn+m|\hat{\mathcal{H}}_F|pn+m\rangle \approx \langle qm|\hat{\mathcal{H}}_F|qm\rangle = \blacksquare$ for all m , that are not directly connected via an off-resonance element $\bullet$. The procedure creates an approximate Floquet matrix $\hat{\mathcal{H}}'_F$ with off-diagonal elements between the degenerate states, and eliminates off-diagonal elements in $\hat{\mathcal{H}}_F$ that are small with respect to the difference between the diagonal elements they connect. The correction element can be calculated according to

$$\langle pn+m|\hat{\mathcal{H}}'_F|qm\rangle = \sum_{r,s} \sum_{k,l=-\infty}^{\infty} \frac{\langle pn+m|\hat{\mathcal{H}}_F|rk\rangle \langle rk|\hat{\mathcal{H}}_F|sl\rangle \langle sl|\hat{\mathcal{H}}_F|qm\rangle}{(E_n^{pq} - \langle rk|\hat{\mathcal{H}}_F|rk\rangle)(E_n^{pq} - \langle sl|\hat{\mathcal{H}}_F|sl\rangle)} \\ + \dots = \blacklozenge$$

This shows that degenerate Floquet states will be shifted away from each other, even when the interaction Hamiltonian does not exactly exhibit matrix elements between these states

If all off-diagonal elements of $\hat{\mathcal{H}}_F$ are much smaller than the differences between the diagonal elements they connect, standard perturbation theory^{16–18,36} can be exploited to estimate eigenvalues and eigenvectors. For example, Nakai et al.²⁸ used nondegenerate perturbation theory to very high orders for calculating the eigenvalues of the Floquet Hamiltonian of rotating homonuclear two-spin systems. Augustine et al.²⁹ used perturbation theory to evaluate second-order effects in heteronuclear spin systems.

If some off-diagonal elements connect degenerate diagonal elements of $\hat{\mathcal{H}}_F$, zeroth-order 2×2 diagonalization must be performed before a higher-order perturbation expansion can be used. This is commonly necessary for evaluating the energy shifts of the levels at anticrossings (see Section 3.3). However, if the degenerate diagonal elements are not directly connected via nonzero off-diagonal elements, the off-diagonal perturbation approach³ can be used to estimate an effective off-diagonal element between these degenerate elements (see also the example in Section 4.1). An example of this approach can be found in the paper of Krauss et al.,²³ in which multiphoton effects in NMR on spins with $I = \frac{1}{2}$ are discussed. While the standard perturbation theory approach modifies the diagonal elements and eliminates off-diagonal elements of the Hamiltonian, the off-diagonal perturbation approach replaces existing off-diagonal elements by new small off-diagonal elements between almost-degenerate states (see Figure 7).

3 STROBOSCOPIC DETECTION

3.1 Evolution Operators and Expectation Values

The time dependence of the expectation values of observables is governed, according to equation (23), by the differences between the eigenvalues of the Floquet Hamiltonian. If the observation of these expectation values is restricted to times that are integer multiples of the time constant T of the period of the Hamiltonian ($\exp(i\omega_n T) = 1$), the detection is performed stroboscopically. In this case, the matrix elements of the spin evolution operator in equations (13a) and (13b) become

$$\langle p|\hat{U}(n_T T)|q\rangle = \sum_{n=-\infty}^{\infty} \langle pn|\hat{U}_F(n_T T)|q0\rangle \\ = \sum_r \sum_{n,m=-\infty}^{\infty} \langle pn|\hat{D}_F|rm\rangle \\ \times \exp(-i\lambda_m^r n_T T) \langle rm|\hat{D}_F^{-1}|q0\rangle \\ = \left(\sum_{n=-\infty}^{\infty} \langle pn|\hat{D}_F|r0\rangle \right) \exp(-i\lambda_0^r n_T T) \\ \times \left(\sum_{m=-\infty}^{\infty} \langle rm|\hat{D}_F^{-1}|q0\rangle \right) \quad (44)$$

where we have used the definition of the Floquet evolution operator $\hat{U}_F(t)$ and the diagonalization $\hat{\mathcal{H}}_F = \hat{D}_F \hat{\Lambda}_F \hat{D}_F^{-1}$.

Figure 8 In an experiment that allows only stroboscopic detection of the coherences of a spin system, the data are collected once per each time period T of the spin Hamiltonian with $\hat{H}(t + n_T T) = \hat{H}(t)$

The expression for the expectation values of observables in equation (23) can also be simplified during stroboscopic detection (Figure 8):

$$\begin{aligned} \langle \hat{O} \rangle &= \sum_{n=-\infty}^{\infty} \sum_p \langle pn | \hat{R}(t) \hat{O}_F | p0 \rangle \\ &= \sum_{p < q} A^{pq} O^{pq} \exp[-i(\lambda_0^q - \lambda_0^p)n_T T] \end{aligned} \quad (45)$$

with

$$A^{pq} = \sum_{n=-\infty}^{\infty} \langle \lambda_0^p | \hat{R}(0) | \lambda_n^q \rangle, \quad O^{pq} = \sum_{n=-\infty}^{\infty} \langle \lambda_n^q | \hat{O}_F | \lambda_0^p \rangle \quad (46)$$

3.2 Effective Hamiltonians

The spin evolution operator in equation (44) can be written as function of an effective spin Hamiltonian $\hat{\mathcal{H}}_{\text{eff}}$.^{10,17,18,38}

$$\hat{U}(n_T T) = \exp(-i\hat{\mathcal{H}}_{\text{eff}}n_T T) \quad (47)$$

This time-independent Hamiltonian governs the spin system in an exact manner as long as the detection of any observable is restricted to $n_T T$. Comparing equations (47) and (44), the matrix elements of the effective Hamiltonian can be defined by

$$\langle p | \hat{\mathcal{H}}_{\text{eff}} | q \rangle = \langle p | \hat{D} \hat{\Lambda} \hat{D}^{-1} | q \rangle \quad (48)$$

with

$$\left. \begin{aligned} \langle r | \hat{\Lambda} | r \rangle &= \langle r0 | \hat{\Lambda}_F | r0 \rangle = \lambda_0^r \\ \langle p | \hat{D} | r \rangle &= \sum_{n=-\infty}^{\infty} \langle pn | \hat{D}_F | r0 \rangle = \sum_{n=-\infty}^{\infty} d_n^{pr} \end{aligned} \right\} \quad (49)$$

The energies of the effective Hamiltonian are thus equal to the principal eigenvalues of $\hat{\mathcal{H}}_F$, and the elements of its diagonalization matrix are equal to the sums of the elements of $\hat{D}_F$. The principal eigenvalues of $\hat{\mathcal{H}}_F$ can always be chosen

between $\frac{1}{2}\omega$ and $-\frac{1}{2}\omega$,¹⁶⁻¹⁸ as expected for a sampling time of $T = 2\pi/\omega$. The actual evaluation of the effective Hamiltonian is again dependent on the diagonalization of the $\hat{\mathcal{H}}_F$. If this can be achieved then the effective Hamiltonian describes the stroboscopic evolution spin of the system in an exact manner. If not, then again approximation methods, such as perturbation theory, must be utilized. A Floquet Hamiltonian that is block-diagonal has a z -diagonalization matrix that satisfies equation (42) and thus $\langle p | \hat{D} | r \rangle = \delta_{pr}$, and generates a diagonal effective Hamiltonian with elements $\langle p | \hat{\mathcal{H}}_{\text{eff}} | p \rangle = \langle p0 | \hat{\mathcal{H}}_F | p0 \rangle$.

It is desirable to present the effective Hamiltonian in terms of angular momentum operators. Examples are provided by Weintraub and Vega.³⁸ If the diagonalization is performed numerically, the above equations provide the way to represent the effective Hamiltonian in matrix form. This form can always be transformed to an expression in terms of fictitious spin- $\frac{1}{2}$ operators.^{39,40}

3.3 Degenerate Floquet States

Various spectroscopic effects in MAS NMR could be explained by the removal of degeneracies between Floquet states (i.e., the eigenvalues of the Floquet Hamiltonian) of a spin system, due to an interaction Hamiltonian. Rotor frequency lines,²⁶ the rotary resonance,⁴² and the rotational resonance^{30,43} phenomena could all be explained in terms of the removal of such a degeneracy. Even the homonuclear recoupling experiments^{31,32,40} could be described by the anticrossing of Floquet states in the toggling frame.

In order to explain the anticrossing of Floquet states, let us consider a diagonal Floquet Hamiltonian

$$\hat{\mathcal{H}}_F = \sum_p \omega \hat{N}^{pp} + \sum_p 2\omega_{z0}^{pp} \hat{Z}_0^{pp} \quad (50)$$

and an additional interaction term of the form

$$\sum_{n=-\infty}^{\infty} (2\omega_{xn}^{st} \hat{X}_n^{st} + 2\omega_{yn}^{st} \hat{Y}_n^{st}) \quad (51)$$

The matrix elements of this addition are only significant when ω_{xn}^{st} and ω_{yn}^{st} are not much smaller than the difference $\omega_{z0}^{ss} - \omega_{z0}^{tt} + n\omega$ between the Floquet energies of the states they connect. However, if this is the case, the interaction term can shift the energies significantly, and an anticrossing of the Floquet states can occur (Figure 9).

A degeneracy $\omega_{z0}^{ss} + n\omega + m\omega \approx \omega_{z0}^{tt} + m\omega$, for all m , between the eigenstates $|s(m+n)\rangle$ and $|tm\rangle$ of $\hat{\mathcal{H}}_F$ will be lifted by an interaction term that connects these states, and will give new eigenvalues

$$\begin{aligned} &\frac{1}{2}(\omega_{z0}^{ss} + \omega_{z0}^{tt} + n\omega) + m\omega \\ &\pm \{-\frac{1}{2}n\omega + [\frac{1}{4}(\omega_{z0}^{ss} - \omega_{z0}^{tt} + n\omega)^2 + \omega_{xn}^{st2} + \omega_{yn}^{st2}]^{1/2}\} \end{aligned} \quad (52)$$

The part of the effective Hamiltonian that corresponds to the $s-t$ transition will then take the form³⁸

$$\hat{\mathcal{H}}_{\text{eff}}^{st} = (\omega_{z0}^{ss} - \omega_{z0}^{tt} + n\omega) \hat{I}_z^{st} + 2\omega_{xn}^{st} \hat{I}_x^{st} + 2\omega_{yn}^{st} \hat{I}_y^{st} - n\omega \hat{I}_z^{st} \quad (53)$$

Figure 9 A schematic representation of the anticrossing of almost-degenerate eigenfunctions of a Floquet matrix with $\langle sn + m | \hat{\mathcal{H}}_F | sn + m \rangle = \langle tm | \hat{\mathcal{H}}_F | tm \rangle$ that is caused by an interaction matrix element $\Delta \langle sn + m | \hat{\mathcal{H}}_F^{\text{int}} | tm \rangle$

The anticrossing of the Floquet eigenstates will cause frequency shifts in the expectation values of coherences and polarizations of spin systems. This will occur not only in the case of stroboscopic detection but also in the $(\lambda_0^q - \lambda_0^p) + n\omega$ frequencies of nonsynchronously detected observables.

Thus, the effective Hamiltonian for a stroboscopic observation of a spin system is obtained by the construction of the Floquet Hamiltonian and by its diagonalization. The Floquet principal eigenvalues λ_0^q have become equal to the energies of the effective Hamiltonian, and its operational form can be evaluated by summations over matrix elements d_n^{pq} of the Floquet diagonalization matrix. Where necessary, perturbation theory can be exploited to estimate the parameters λ_0^q and d_n^{pq} , and, where accurate results are required, numerical methods can be used. As mentioned before, expansion methods for the evaluation of effective Hamiltonians, as discussed by Maricq¹⁷ and Llor,¹⁸ are not presented in this article.

4 EXAMPLES

In the rest of this article, some examples of the use of the Floquet approach will be discussed. Only the computational steps relevant to Floquet theory are presented in these examples.

4.1 Modulated rf Excitation

4.1.1 Multifrequency Pulse Excitation

An amplitude- and phase-modulated rf excitation pulse of finite length T that is applied to a spin system with $I = \frac{1}{2}$ has a spin Hamiltonian that can be written in the form

$$\begin{aligned} \hat{\mathcal{H}}(t) &= -\Delta\omega\hat{I}_z + 2\omega_x(t)\hat{I}_x + 2\omega_y(t)\hat{I}_y \\ &= -\Delta\omega\hat{I}_z + \sum_{n=-\infty}^{\infty} [2\omega_{xn}\hat{I}_x + 2\omega_{yn}\hat{I}_y] \exp(in\omega t) \end{aligned} \quad (54)$$

Figure 10 An rf irradiation pulse of finite length can be considered as if it is composed of a set of simultaneously applied rf fields at constant frequency intervals ω

with $\omega = 2\pi/T$. The Fourier transformation describes the time-dependent rf field in terms of multifrequency irradiation (Figure 10). The Floquet Hamiltonian corresponding to this Hamiltonian has the following form, when we consider the length of the pulse as its single time period ($|1\rangle = |\alpha\rangle, |2\rangle = |\beta\rangle$):

$$\begin{aligned} \hat{\mathcal{H}}_F &= \omega(\hat{N}^{11} + \hat{N}^{22}) - \Delta\omega\hat{Z}_0^{12} \\ &+ \sum_{n=-\infty}^{\infty} (2\omega_{xn}\hat{X}_n^{12} + 2\omega_{yn}\hat{Y}_n^{12}) \end{aligned} \quad (55)$$

If we are only interested in the state of the spin immediately after the pulse, it is most convenient to evaluate the effective Hamiltonian of the pulse (see Section 3.2).

For small-amplitude coefficients, $\omega_{nx}, \omega_{ny} \ll \omega$, perturbation theory can be used to evaluate this Hamiltonian. For a special case, with $\Delta\omega \ll \omega$ and $\omega_{x0} = \omega_{y0} = 0$ and thus $\langle 1n | \hat{\mathcal{H}}_F | 1n \rangle \approx \langle 2n | \hat{\mathcal{H}}_F | 2n \rangle$, the degenerate perturbation approach can be used in order to obtain an approximate Floquet Hamiltonian of the form²³ (see Section 2.7)

$$\hat{\mathcal{H}}'_F = \omega(\hat{N}^{11} + \hat{N}^{22}) - (\Delta\omega + \delta\omega)\hat{Z}_0^{12} + \omega_{\text{eff}}\hat{P}_0^{12} + \omega_{\text{eff}}^*\hat{M}_0^{12} \quad (56)$$

with

$$\omega_{\text{eff}} = \sum_{k,l=-\infty}^{\infty} \frac{\langle 10 | \hat{\mathcal{H}}_F | 2k \rangle \langle 2k | \hat{\mathcal{H}}_F | 1l \rangle \langle 1l | \hat{\mathcal{H}}_F | 20 \rangle}{(E_0^{12} - \langle 2k | \hat{\mathcal{H}}_F | 2k \rangle)(E_0^{12} - \langle 1l | \hat{\mathcal{H}}_F | 1l \rangle)} + \dots \quad (57)$$

$$\begin{aligned} \delta\omega &= - \sum_{k,l=-\infty}^{\infty} \frac{\langle 10 | \hat{\mathcal{H}}_F | 2k \rangle \langle 2k | \hat{\mathcal{H}}_F | 10 \rangle}{(E_0^{12} - \langle 2k | \hat{\mathcal{H}}_F | 2k \rangle)} \\ &- \frac{\langle 20 | \hat{\mathcal{H}}_F | 1k \rangle \langle 1k | \hat{\mathcal{H}}_F | 20 \rangle}{(E_0^{12} - \langle 1k | \hat{\mathcal{H}}_F | 1k \rangle)} + \dots \end{aligned} \quad (58)$$

and $E_n^{12} = \frac{1}{2}[\langle 1n | \hat{\mathcal{H}}_F | 1n \rangle + \langle 2n | \hat{\mathcal{H}}_F | 2n \rangle]$. This approximate Hamiltonian contains only corrected diagonal elements and small off-diagonal elements, connecting the almost-degenerate diagonal elements. All other off-diagonal elements are discarded from the Hamiltonian.

The Floquet Hamiltonian in equation (56) generates an effective Hamiltonian of the form

$$\hat{\mathcal{H}}_{\text{eff}} = -(\Delta\omega + \delta\omega)\hat{I}_z + \omega_{\text{eff}}\hat{I}_+ + \omega_{\text{eff}}^*\hat{I}_- \quad (59)$$

When the pulse exhibits only four frequency components, $\omega_{x\pm n} \neq 0$ for $n = n_1, \pm n_2$, equation (59) represents the effective Hamiltonian of an $(n_1 + n_2)$ -photon pulse.²³

4.1.2 Pulse Shaping

For arbitrary frequency amplitudes in the spin Hamiltonian of the excitation pulse in equation (54), numerical diagonalizations of its Floquet Hamiltonian can be performed in order to obtain the eigenvalues $\pm\lambda_0^1$ and the matrix elements d_n^{pq} of the diagonalization matrix of $\hat{\mathcal{H}}_F$. Insertion of these results in equations (48) and (49) in Section 3.2 will yield the effective Hamiltonian.

For designing frequency-selective pulses, the form of the required effective Hamiltonian can be defined, and conditions for $\pm\lambda_0^1$ and the sums of the d_n^{pq} elements, as a function of the off-resonance, can be determined. Numerical search procedures can then be utilized to obtain optimal ω_{xn} and ω_{yn} values that will satisfy these conditions.²⁴ For example, a broadband pulse that requires an effective Hamiltonian $\hat{\mathcal{H}}_{\text{eff}} = \omega_1 \hat{I}_x$ for a large range of off-resonance values $\Delta\omega$, must satisfy the condition $\lambda_0^1 = 0.5\omega_1$, and $\sum_n d_n^{11} = -\sum_n d_n^{12} = \sqrt{\frac{1}{2}}$ for its Floquet Hamiltonian.

If the Floquet approach is used to design TOCSY sequences,⁶ the calculation of the effective Hamiltonian is not sufficient, and all the individual elements of $\hat{D}_F$ become relevant.⁴⁴

4.2 Magic Angle Spinning NMR

4.2.1 MAS Sideband Spectra

The Hamiltonian of a spin system with $I = \frac{1}{2}$ in a single crystallite of a polycrystalline solid that is rotating at the magic angle with a spinning speed ω_R can be written in the form⁴⁵

$$\begin{aligned} \hat{\mathcal{H}}_{\text{CS}}(t) &= -\Delta\omega \hat{I}_z + \omega_{\text{CS}}[g_1 \cos(\omega_R t + \psi_1) \\ &\quad + g_2 \cos(2\omega_R t + \psi_2)] \hat{I}_z \\ &= -\Delta\omega \hat{I}_z + \sum_{n=-2, n \neq 0}^2 2\omega_n^{\text{CS}} \exp(in\omega_R t) \hat{I}_z \end{aligned} \quad (60)$$

The chemical shift parameter ω_{CS} and the explicit forms of the orientational dependent parameters g_n , ψ_n , and $\omega_n^{\text{CS}} = \frac{1}{4}\omega_{\text{CS}}g_{|n|}\exp(in\psi_n)$, can be derived from the MAS Hamiltonians given in **Magic Angle Spinning**. The Floquet Hamiltonian corresponding to this Hamiltonian is block-diagonal,

$$\hat{\mathcal{H}}_F^{\text{CS}} = \omega_R(\hat{N}^{11} + \hat{N}^{22}) - \Delta\omega \hat{Z}_0^{12} + \sum_{n=-2, n \neq 0}^2 2\omega_n^{\text{CS}} \hat{Z}_n^{12} \quad (61)$$

and can be z -diagonalized. Its principal eigenvalues are $\lambda_0^1 = \frac{1}{2}\Delta\omega$, and the elements of its diagonalization matrix satisfies $d_n^{11} = d_{-n}^{22*}$, according to the discussion at the end of Section 2.6. The FID signal (ignoring relaxation) after a simple

excitation of the rotating spin system, with $\hat{\rho}(0) = 2\hat{I}_x$ and $\hat{R}(0) = 2\hat{X}_0^{12}$, is equal to

$$\begin{aligned} \langle \hat{I}_- \rangle &= \sum_{n=-\infty}^{\infty} A^{12} \langle \lambda_n^2 | \hat{M}_0^{12} | \lambda_0^1 \rangle \exp[i(\lambda_n^2 - \lambda_0^1)t] \\ &= \exp(i\Delta\omega t) \sum_{n,m=-\infty}^{\infty} d_{-n-m}^{11} d_m^{11} \exp(in\omega_R t) \end{aligned} \quad (62)$$

with

$$|\lambda_n^1\rangle = \sum_{m=-\infty}^{\infty} d_m^{11} |1n\rangle \quad (63)$$

and, according to equation (42) in Section 2.6,

$$A^{pq} = \sum_{n=-\infty}^{\infty} \langle \lambda_0^1 | \hat{X}_0^{12} | \lambda_n^2 \rangle = \sum_{n,m=-\infty}^{\infty} d_m^{11*} d_{n+m}^{22} = 1 \quad (64)$$

The Fourier transform of the total signal of all crystallites in the sample results in a sideband spectrum. The amplitudes of these frequency bands are equal to the powder integrals of the amplitudes of the individual allowed transitions between Floquet states (see Figure 3). An elegant methodology, similar to the Floquet approach, for the calculation of MAS spectra was introduced by Sethi et al.⁴⁶

4.2.2 Rotor Frequency Lines

If the rotating spin system experiences a weak rf field during signal detection (e.g., a nonzero effective rf field during a multiple pulse experiment²⁶), a term $\omega_1 \hat{I}_x$ must be added to $\hat{\mathcal{H}}_{\text{CS}}(t)$ and a term $\omega_1 \hat{X}_0^{12}$ to $\hat{\mathcal{H}}_F^{\text{CS}}$ with $\omega_1 \ll \omega_R$. The matrix elements of $\hat{X}_0^{12}$ connect the $|1n\rangle$ and $|2n\rangle$ states with Floquet energies $-\frac{1}{2}\Delta\omega + n\omega_R$ and $\frac{1}{2}\Delta\omega + n\omega_R$. These elements can change the eigenvalues and eigenvectors of $\hat{\mathcal{H}}_F$ significantly, even if degeneracies occur between diagonal elements with different n values. For example, when $\Delta\omega \approx n\omega_R$, the Floquet states $|1(n+m)\rangle$ and $|2m\rangle$ for all m are degenerate, and an energy anticrossing can occur. For estimating the dependence on the irradiation term of this energy shift, a z diagonalization of $\mathcal{H}_F$, by a diagonal block matrix $\hat{D}_F$, can be performed (see Section 2.6), and the matrix elements $\delta\omega_1(n) = \frac{1}{2}\omega_1 \langle 1n+m | \hat{D}_F \hat{X}_0^{12} \hat{D}_F^{-1} | 2m \rangle$ between the degenerate states can be evaluated. When this element is different from zero, an effective Hamiltonian of the form (see Sections 3.2 and 3.3)

$$\begin{aligned} \hat{\mathcal{H}}_{\text{eff}}(\Delta\omega \approx n\omega_R) &= -(\Delta\omega - n\omega_R) \hat{I}_z + \delta\omega_1(n) \hat{I}_+ \\ &\quad + \delta\omega_1^*(n) \hat{I}_- \end{aligned} \quad (65)$$

will be obtained. Thus, for stroboscopic measurements, the main resonances are expected at frequencies $[(\Delta\omega - n\omega_R)^2 + 4\delta\omega_1^2(n)]^{1/2}$ and 0, and for nonstroboscopic experiments at

Figure 11 Nitrogen-15 NMR MAS spectrum of doubly ^{15}N -labeled glycylglycine that demonstrates the rotor frequency lines. This spectrum was obtained by a MAS scaling experiment with $q = 0.50$ and $\nu_R = \omega_R/2\pi = 1.67\text{ kHz}$. The additional lines in the spectrum are clearly observed at the $(k + n)\omega_R$ positions, when the offset frequency of one of the lines satisfies $\Delta\omega \approx k\omega_R$. (Adapted by permission from Ave et al.²)

$[(\Delta\omega - n\omega_R)^2 + 4\delta\omega_1^2(n)]^{1/2} + m\omega_R$ and $nm\omega_R$. An example of rotor frequency lines is shown in Figure 11.

4.2.3 Rotational Resonance

The Floquet approach can also be applied to explain the rotational resonance phenomena^{43,47} that occur when the interaction between two dipolar-coupled homonuclear spins is monitored during an MAS experiment. If the strength of the interaction is smaller than the spinning speed, the sample rotation will largely eliminate its influence on the MAS spectra of the spins. However, if the difference between the isotropic shifts of the two spins $\Delta\omega = \Delta\omega^{(1)} - \Delta\omega^{(2)}$ is approximately equal to an integer multiple of the spinning frequency ω_R , the interaction will influence the spin evolution significantly. To demonstrate this effect, we can consider the Floquet space defined by the states $\{|pn\rangle\}$, with $p = 1, \dots, 4$, $|1\rangle = |\alpha\alpha\rangle$, $|2\rangle = |\alpha\beta\rangle$, $|3\rangle = |\beta\alpha\rangle$, and $|4\rangle = |\beta\beta\rangle$. The chemical shift parts of the two spins of the Floquet Hamiltonian as well as the main parts of the dipolar interaction, corresponding to the $\hat{I}_{z1}\hat{I}_{z2}$ terms in the spin Hamiltonian, are block diagonal [see equation (61)]. Only the flip-flop terms, corresponding to $\frac{1}{4}(\hat{I}_{+1}\hat{I}_{-2} + \hat{I}_{-1}\hat{I}_{+2})$, contribute to the off-diagonal blocks 2–3. The terms in the Floquet Hamiltonian corresponding to these blocks have the form $\omega_d \sum_n G_n \hat{X}_n^{23}$, $n = -2, -1, 1, 2$. They connect the states $|2n + m\rangle$ and $|3m\rangle$, for $n = \pm 1, \pm 2$ and all m , with Floquet energies $-\frac{1}{2}\Delta\omega + (n + m)\omega_R$ and $\frac{1}{2}\Delta\omega + m\omega_R$, respectively.^{30,32,41} These elements will

influence the eigenvalues of the whole Floquet Hamiltonian most significantly when they connect degenerate Floquet states, i.e., $\Delta\omega = n\omega_R$. Energy shifts are also expected for n values different from $\pm 1, \pm 2$. The changes in the eigenvalues influence the time dependences of the expectation values of the spin angular momentum operators, and thus modify the time dependence of the coherences and populations of the spin system and its MAS spectra.⁴²

4.2.4 Effective Hamiltonians of Multipulse Experiments

When rf pulses are applied to rotating spin systems synchronously with the spinning speed, effective Hamiltonians can be evaluated by transforming the spin Hamiltonian to the toggling frame.⁵ In that case, the rf terms in the spin Hamiltonian become periodically time-dependent, and a Fourier transformation of these terms is possible. Using the Fourier coefficients of this transformation, a Floquet Hamiltonian that corresponds to the toggling-frame spin Hamiltonian can be constructed. This Hamiltonian governs the spin system again, as long as the toggling-frame transformation is cyclic.^{5,11} Examples of this approach can be found in the literature.^{31,38,47}

4.2.5 CP MAS Experiments

One of the most important developments in high-resolution solid state NMR spectroscopy was the introduction of cross polarization MAS (CP MAS) experiments on low-abundance $I = \frac{1}{2}$ spins by Schaefer and Stejskal.⁴⁸ Floquet theory can provide an elegant way to derive the Hartmann–Hahn conditions of these experiments.^{49,50}

The simplest spin system to be considered in order to derive the Hartmann–Hahn condition of CP MAS experiments consists of a high-abundance dipolar-coupled homonuclear spin system (almost always protons) and a single (low-abundance) heteronuclear spin (e.g., $X = ^{13}\text{C}$ or ^{15}N).⁵¹ When the high- and low-abundance spins are irradiated simultaneously with CW rf fields of intensities ω_{1H} and ω_{1X} , respectively, an energy level manifold $\{|M\alpha\rangle, |M\beta\rangle\}$ in the doubly rotating frame can be chosen.⁴ M are the eigenvalues of the component of the total angular momentum of the abundant spins in the direction of their rf field. α and β are the spin-up and spin-down states of the low-abundance spin in the direction of its rf field. Each state $|M\alpha\rangle$ represents an ensemble of homonuclear coupled spin states. In a rotating sample the dipolar interactions between the spins in the system are periodically time dependent, and the spin Hamiltonian can be replaced by a Floquet Hamiltonian, defined in a manifold of dressed states $\{|Man\rangle, |M\beta n\rangle\}$.

The heteronuclear dipolar interaction is also periodically time-dependent, and connects the Floquet states $|M\alpha m\rangle$ with $|M + 1\beta m + n\rangle$, owing to its terms in the spin Hamiltonian of the form $\sum_i \omega_{in}^{dip} \hat{I}_{zi} \hat{S}_z \exp(in\omega_R t)$. Thus, in the manifold of Floquet states $\{|Man\rangle, |M\beta n\rangle\}$, the heteronuclear interaction generates off-diagonal elements. These elements can only have a real influence on the spin system when the above-mentioned Floquet states are almost degenerate. Their Floquet energies are equal to $M\omega_{1H} + \frac{1}{2}\omega_{1X} + \langle\omega(M, m)\rangle + m\omega_R$ and $(M + 1)\omega_{1H} - \frac{1}{2}\omega_{1X} + \langle\omega(M + 1, n + n)\rangle + (m + n)\omega_R$, respectively, where the $\langle\omega(M, m)\rangle$ terms represent the level

Figure 12 A demonstration of the cross-polarization MAS experiment. The Floquet energy level diagram of an abundant homonuclear spin system, interacting with a single heteronuclear spin, is shown. The states $\{|M\alpha n\rangle, |M\beta n\rangle\}$ of this system, while irradiated by two rf fields, are defined in the text. A degeneracy between the states $|M+1\beta m+n\rangle$ and $|M\alpha m\rangle$ enables the heteronuclear dipolar interaction to equilibrate their initial spin populations. If at the start of the cross-polarization process the populations of these states are proportional to $(M+1)\omega_{0H}$ and $M\omega_{0H}$, and at the end of the process these populations are equilibrated, i.e., $(M+\frac{1}{2})\omega_{0H}$, the signal of the low abundance spin becomes proportional to the population difference of the states $|M\alpha n\rangle$ and $|M\beta 0\rangle$, i.e., $[(M+\frac{1}{2}) - (M-\frac{1}{2})]\omega_{0H} = \omega_{0H}$

distribution inside the m th Floquet M manifold (Figure 12). Equilibration of these energies maximizes the influence of the heteronuclear dipolar interaction, defines the Hartmann–Hahn conditions, and enables the cross polarization process for the signal enhancement of the X spin system:

$$\omega_{1H} \approx \omega_{1X} + n\omega_R \quad (66)$$

The spin dynamics of the cross-polarization process can also be described in terms of the Floquet approach. Extensions of this description to low-abundance spins with $I = 1$ can also be made.

4.2.6 Dynamic MAS NMR

Chemical exchange processes in rotating spin systems will influence their MAS sideband spectra. To evaluate these dynamic MAS spectra, various efficient methodologies have been introduced.⁵² One of the alternatives for these calculations is the Floquet theory approach.^{33,34} With this, an infinite Floquet exchange matrix can be constructed, composed of the coefficients of an infinite set of Bloch–McConnell equations, for the signal components of the exchanging spin

systems. The solution of this equation enables the evaluation of the dynamic MAS spectra.

Let us consider a set of spin systems with $I = \frac{1}{2}$ at different sites in a rotating solid with chemical shift Hamiltonians $\hat{\mathcal{H}}^M(t)$ and Floquet matrices $\hat{\mathcal{H}}_F^M$. The signal of the spins at a site M is proportional to $\langle \hat{I}_-^M \rangle$. In Floquet space, this expectation value $S^M(t) = \langle \hat{I}_-^M \rangle(t)$ can be expressed according to equation (21) in Section 2.4, in terms of the Floquet density matrix $\hat{R}^M(t)$ and the lowering operator $\hat{M}_0^{12,M}$:

$$S^M(t) = \sum_{n=-\infty}^{\infty} \langle 1_{Mn} | \hat{R}(t) | 2_{M0} \rangle \langle 2_{M0} | \hat{M}_0^{12,M} | 1_{M0} \rangle \exp(in\omega_R t) \quad (67)$$

where $|\alpha_M\rangle = |1_M\rangle$, $|\beta_M\rangle = |2_M\rangle$. With $\langle 2_{M0} | \hat{M}_0^{12,M} | 1_{M0} \rangle = 1$, signal coefficients can be defined as

$$s_n^M(t) = \langle 1_{Mn} | \hat{R}^M(t) | 2_{M0} \rangle \quad (68)$$

in order to express the signal of site M as

$$S^M(t) = \sum_{n=-\infty}^{\infty} s_n^M(t) \exp(in\omega_R t) \quad (69)$$

A rate equation for the coefficients $s_n^M(t)$ can easily be derived from the equation of motion of $\hat{R}^M(t)$ [equation (16) in Section 2.3]:

$$\begin{aligned} \frac{d}{dt} s_n^M(t) = & -i \sum_{m=-\infty}^{\infty} \{ \langle 1_{Mn} | \hat{\mathcal{H}}_F^M | 1_{Mm} \rangle - \langle 2_{Mn} | \hat{\mathcal{H}}_F^M | 2_{Mm} \rangle \\ & + (n-m)\omega_R \} s_m^M(t) \end{aligned} \quad (70)$$

This set of equations can be rewritten in a vector–matrix form as

$$\frac{d}{dt} \mathbf{s}^M(t) = -i\mathbf{\Omega}^M \mathbf{s}^M(t) \quad (71)$$

where the vector $\mathbf{s}^M(t)$ and the matrix $\mathbf{\Omega}^M$ are defined in some infinite manifold of states $\{|n_M\rangle\}$:

$$\left. \begin{aligned} \mathbf{s}(t) &= \sum_{n=-\infty}^{\infty} s_n^M(t) |n_M\rangle \\ \langle n_M | \mathbf{\Omega}^M | m_M \rangle &= \langle 1_n | \hat{\mathcal{H}}_F^M | 1_m \rangle - \langle 2_n | \hat{\mathcal{H}}_F^M | 2_m \rangle + n\delta_{nm} \end{aligned} \right\} \quad (72)$$

The solution of equation (71), together with equation (69), provides the FID MAS signal of site M .

For a dynamic process that exchanges spins between sites $M = \text{I, II, } \dots, N$ with rate constants k_{KL} , the Bloch–McConnell equations can be written in the form⁵³

$$\frac{d}{dt} \mathbf{s}^M(t) = -i\mathbf{\Omega}^M \mathbf{s}^M(t) - \sum_{K=\text{I}}^N k_{MK} [\mathbf{s}^M(t) - \mathbf{s}^K(t)] \quad (73)$$

The solution of these coupled equations allows the evaluation of the dynamic MAS spectra. These equations can also be

represented in matrix form, when we define a manifold of states $\{|Mn_M\rangle\}$:

$$\frac{d}{dt}\mathbf{S}(t) = -i\bar{\Omega}\mathbf{S}(t) \quad (74)$$

with the Floquet signal vector

$$\mathbf{S}(t) = \sum_{M=1}^N \sum_{n=-\infty}^{\infty} s_n^M(t) |Mn_M\rangle \quad (75)$$

and the Floquet exchange matrix elements

$$\left. \begin{aligned} \langle\langle Mn_M | \bar{\Omega} | Mm_M \rangle\rangle &= \langle\langle n_M | \Omega^M | m_M \rangle\rangle - i \sum_{K=1}^N k_{MK} \delta_{n_M m_M} \\ \langle\langle Mn_M | \bar{\Omega} | Km_K \rangle\rangle &= ik_{MK} \delta_{n_M m_K} \end{aligned} \right\} \quad (76)$$

The construction of this exchange matrix is straightforward, as long as the Hamiltonians of the different sites are known. The Fourier components of these Hamiltonians compose the matrices Ω^M . Their insertion in $\bar{\Omega}$ generates this exchange matrix. A numerical diagonalization of a truncated form of this matrix provides the solution of equation (74) and allows the evaluation of the time dependence of the elements of the vector $\mathbf{S}$:

$$\mathbf{S}(t) = \exp(-i\bar{\Omega}t)\mathbf{S}(0) \quad (77)$$

The sum of all elements of the vector $\mathbf{S}(t)$, according to equation (69),

$$\mathbf{S}(t) = \sum_{M=1}^N \sum_{n=-\infty}^{\infty} s_n^M(t) \exp(in\omega_R t) \quad (78)$$

then provides the FID signal of the exchanging spin system.³⁴

1 INTRODUCTION

NMR spectroscopy in the solid state has evolved from CW spectroscopy^{1,2} via the pulsed and spin echo experiments³ of the early days to a highly sophisticated spectroscopic technique which allows one to distinguish and determine very subtle nuclear spin interactions either with other nuclear spins or with electrons in any type of solid material.^{4–6} Because of the local property of these interactions, information not only on crystalline solids but also on disordered materials (amorphous solids, glasses, polymers, etc.) can be obtained. This makes NMR spectroscopy in the solid state complementary to many other spectroscopic techniques, such as optical spectroscopy. With the advent of special high-resolution techniques for solids,^{7–10} different nuclear spin interactions could be resolved, and detailed information on the spatial and electronic structure of solids has become available. The sevenfold ways¹⁰ that nuclear spins can interact with their environment in solid materials are summarized schematically in Figure 1.

External magnetic fields B_0 and B_1 are usually applied to the sample and also to the nuclear spins (path 1). These fields basically serve the purpose of creating and manipulating the quantum states of the nuclear spins. The most elementary spin–spin interaction is the direct dipole–dipole interaction between nuclear spins (path 2). The dominant contribution to internal interactions of nuclear spins in solids is, however, due to the electron–nucleus interaction (path 3). It is responsible for such interactions as the chemical shift,¹¹ the Knight shift,¹² quadrupolar interactions,¹³ and indirect spin–spin interactions.^{14–16} The coupling to phonons (path 4) occurs only in an indirect way and is rather weak, and in general leads only to relaxation phenomena.

Relaxation will not be discussed in this article. I shall restrict myself to the discussion of spectral features and give an introduction to how internal spin interactions influence NMR spectra. In addition, I shall give a brief account of how these quantities might be calculated. Spatial and spin space rotations play an important role in solid state NMR. I shall address the question of how rotations affect the spectra and what kind of mathematical techniques are required to deal with these. The discussion will be restricted to ‘basic NMR spectra’ that are typically obtained by Fourier transformation of the FID after

Figure 1 The sevenfold ways a nuclear spin can interact with its environment. The different pathways (1–7) are discussed in the text. (Reproduced by permission of Springer-Verlag from M. Mehring, *Principles of High Resolution NMR in Solids*, Springer-Verlag, Berlin, 1983, p. 8)

pulsed excitation. In many cases, however, special multiple pulse techniques are a prerequisite in order to obtain basic NMR spectra of the kind discussed here, because ‘unwanted interactions’ have to be eliminated first. Nevertheless, no multiple pulse techniques will be discussed in this article. The interested reader is referred to the appropriate articles in the Encyclopedia as well as to special reviews.^{9,10,17,18}

2 NUCLEAR SPIN HAMILTONIAN OPERATORS

NMR spectra are determined by the initial density matrix¹⁹ $\hat{\rho}_0$ and the spin Hamiltonian operators $\hat{\mathcal{H}}$, which we will refer to in the following simply as the ‘Hamiltonian’. As in usual spectroscopic theory the eigenvalues E_j and eigenstates $|j\rangle$ of the Hamiltonian can be calculated, leading to dipole-allowed transitions at frequency $\omega_{ij} = (E_i - E_j)/\hbar$ with strength $|\langle i|\hat{I}_+|j\rangle|^2$, which results in the NMR line intensity

$$I_{ij} = |\langle i|\hat{I}_+|j\rangle|^2(p_i - p_j) \quad (1)$$

where p_i and p_j are the populations of the eigenstates or, equivalently, the diagonal elements of the initial density matrix $\hat{\rho}_0$. Because of the flexibility of NMR in manipulating the initial density matrix and the effective Hamiltonian by well-defined pulse sequences the calculation of NMR spectra proceeds, however, in a more advanced way via the calculation of the response function in the time domain (FID) followed by a Fourier transformation. The FID is, of course, governed by the effective Hamiltonian of the internal interaction. The most common Hamiltonian, that for internal interactions in solids, will thus be described in this section.

Guided by Figure 1 we distinguish spin interactions caused by external and internal fields,

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_{\text{ext}} + \hat{\mathcal{H}}_{\text{int}} \quad (2)$$

where the external fields are the static magnetic field B_0 , which is usually applied parallel to the z axis of the laboratory

2 INTERNAL SPIN INTERACTIONS AND ROTATIONS IN SOLIDS

frame, and $\mathbf{B}_{\text{rf}}$, which is a time-dependent radiofrequency field applied in the (x,y) plane of the laboratory frame, leading to the ‘external’ Hamiltonian:

$$\hat{\mathcal{H}}_{\text{ext}} = \hat{\mathcal{H}}_0 + \hat{\mathcal{H}}_{\text{rf}} \quad (3)$$

which can be summarized as

$$\hat{\mathcal{H}}_{\text{ext}} = \hbar\omega_0 \hat{I}_z + \hbar\omega_{\text{rf}}(e^{i\omega t} + e^{-i\omega t}) \hat{I}_{x,y} \quad (4)$$

where $\omega_0 = -\gamma B_0$ and $\omega_{\text{rf}} = -\gamma B_{\text{rf}}$. The internal interactions can be represented as a sum of different contributions:

$$\hat{\mathcal{H}}_{\text{int}} = \hat{\mathcal{H}}_S + \hat{\mathcal{H}}_Q + \hat{\mathcal{H}}_{II} + \hat{\mathcal{H}}_{IS} + \hat{\mathcal{H}}_{SS} \quad (5)$$

where the first term is due to shielding contributions, the second term represents the quadrupolar interaction caused by electric field gradients, and the last three terms summarize direct and indirect spin–spin interactions, where two different types of nuclear spins, namely I and S spins, are considered. In order to compare different Hamiltonians, we define

$$\|\hat{\mathcal{H}}\| = [\text{Tr}(\hat{\mathcal{H}}^2)]^{1/2} \quad (6)$$

as the ‘magnitude’ of a Hamiltonian, where Tr refers to the ‘trace operation’. In solids, most of the interactions can be represented by second-rank tensors, leading to the following general formulation of internal interactions in Cartesian coordinates of the laboratory frame (xyz) :

$$\hat{\mathcal{H}}_{\text{int}} = \hbar \hat{\mathbf{I}} \cdot \mathbf{A} \cdot \hat{\mathbf{X}} = \hbar (\hat{I}_x \quad \hat{I}_y \quad \hat{I}_z) \begin{pmatrix} A_{xx} & A_{xy} & A_{xz} \\ A_{yx} & A_{yy} & A_{yz} \\ A_{zx} & A_{zy} & A_{zz} \end{pmatrix} \begin{pmatrix} \hat{X}_x \\ \hat{X}_y \\ \hat{X}_z \end{pmatrix} \quad (7)$$

where $\hat{\mathbf{I}}$ is a nuclear spin operator, $\mathbf{A}$ is the interaction tensor, and $\hat{\mathbf{X}}$ may be a magnetic field or another nuclear spin or angular momentum operator. In general, nine different components of the interaction Hamiltonian exist, depending on the local symmetry of the nucleus and the type of interaction. Since rotations either in real space or in spin space play an important role, it is convenient to express the interaction Hamiltonian in addition in the form of spherical tensors $A^{(l,m)}$ and spherical tensor operators $\hat{T}^{(l,m)}$ (for details see the literature^{9, 10, 20, 21}),

$$\hat{\mathcal{H}}_{\text{int}} = \hbar \sum_{l=0}^{l_{\text{max}}} \sum_{m=-l}^{+l} (-1)^m A^{(l,m)} \hat{T}^{(l,-m)} \quad (8)$$

which, when expanded explicitly, is represented by nine different terms (for $l_{\text{max}} = 2$):

$$\begin{aligned} \hat{\mathcal{H}}_{\text{int}} = & \hbar \{ A^{(0,0)} \hat{T}^{(0,0)} + A^{(1,0)} \hat{T}^{(1,0)} \\ & - (A^{(1,1)} \hat{T}^{(1,-1)} + A^{(1,-1)} \hat{T}^{(1,1)}) \\ & + A^{(2,0)} \hat{T}^{(2,0)} - (A^{(2,1)} \hat{T}^{(2,-1)} \\ & + A^{(2,-1)} \hat{T}^{(2,1)}) + A^{(2,2)} \hat{T}^{(2,-2)} + A^{(2,-2)} \hat{T}^{(2,2)} \} \end{aligned} \quad (9)$$

where the $A^{(0,0)}$ component represents the isotropic and the $A^{(1,m)}$ components the antisymmetric parts of the interaction, respectively. Although the antisymmetric part may not be zero (as in chemical shift and indirect spin–spin interactions) it does not contribute to the NMR spectrum. In spin–lattice relaxation, however, these parts do contribute. Since we are concentrating on NMR spectra here, the $A^{(1,q)}$ terms will be neglected in the following. In Section 5.4 the spherical

tensor representation of the internal interactions discussed in this article is summarized. The basic advantage of spherical tensor notation over Cartesian tensors is their transformation properties under rotations. These will be utilized in Section 2.5.

2.1 Chemical Shift and Knight Shift

Soon after the discovery of NMR, it was realized that the resonance frequency of the nuclear spins deviates from the bare nuclear Larmor frequency.^{11, 22, 23} The chemical shift¹¹ and the Knight shift¹² belong to the class of spin interactions characterized by spin Hamiltonians that are linear in spin operators and can be expressed in Cartesian form by the generalized shift Hamiltonian responsible for line shifts of the spectra,

$$\hat{\mathcal{H}}_S = \hbar \hat{\mathbf{I}} \cdot \mathbf{S} \cdot \mathbf{B} \quad (10a)$$

with

$$\mathbf{S} = -\gamma_I \begin{pmatrix} K_{xx} - \sigma_{xx} & K_{xy} - \sigma_{xy} & K_{xz} - \sigma_{xz} \\ K_{yx} - \sigma_{yx} & K_{yy} - \sigma_{yy} & K_{yz} - \sigma_{yz} \\ K_{zx} - \sigma_{zx} & K_{zy} - \sigma_{zy} & K_{zz} - \sigma_{zz} \end{pmatrix} \quad (10b)$$

which contains both the chemical shift and the Knight shift. This is justified because of their similar spin structure in the Hamiltonian. After all, both result from magnetic electron–nuclear coupling; the chemical shift from closed shell electrons, and the paramagnetic or Knight shift from open shell or conduction electron spin interactions with the nuclear spin. This type of paramagnetic shift should not be confused with the paramagnetic contribution to the chemical shift, which is a closed shell property (see Section 5.1). The different sign convention is historical, and stems from the early observation of mostly diamagnetic chemical shifts, which are negative (shielding), in contrast to paramagnetic and Knight shifts, which are, in most cases, positive (depending, however, on the sign of the hyperfine interaction). Both the chemical and Knight shifts can be expressed phenomenologically as ratios of field or frequency shifts with respect to the static magnetic field or Larmor frequency:

$$\sigma_{\alpha\beta} = -\frac{\Delta B_{\alpha\beta}}{B_0} = -\frac{\Delta\omega_{\alpha\beta}}{\omega_0}, \quad K_{\alpha\beta} = \frac{\Delta B_{\alpha\beta}}{B_0} = \frac{\Delta\omega_{\alpha\beta}}{\omega_0} \quad (11)$$

With the conventional orientation of the magnetic field $\mathbf{B}_0 = (0,0,B_0)$, we obtain

$$\hat{\mathcal{H}}_S = -\hbar\gamma_I [(K_{xz} - \sigma_{xz}) \hat{I}_x + (K_{yz} - \sigma_{yz}) \hat{I}_y + (K_{zz} - \sigma_{zz}) \hat{I}_z] B_0 \quad (12)$$

Note that this notation for the shift Hamiltonian is exact in the sense that no high field approximation has been invoked. The influence of the shift Hamiltonian on NMR spectra and their analysis is briefly discussed in Section 3.1. The physical origin of the different parts of the shift Hamiltonian will be outlined briefly in Sections 5.1 and 5.2.

2.2 Quadrupolar Interactions

The quadrupolar interaction arises from the coupling of an electric field gradient $\mathbf{V} = \{V_{\alpha\beta}\}$ (where $\alpha, \beta = x, y, z$) with the nuclear quadrupole moment Q . The corresponding spin Hamiltonian is bilinear in the spin operator, and can be formally expressed in Cartesian form as

$$\hat{\mathcal{H}}_Q = \hbar \hat{\mathbf{I}} \cdot \mathbf{Q} \cdot \hat{\mathbf{I}} \quad (13)$$

where

$$\mathbf{Q} = K_Q \mathbf{V} \quad (14)$$

with $K_Q = eQ/[2I(2I - 1)\hbar]$ and $\mathbf{V} = \{V_{\alpha\beta}\}$, is the quadrupolar interaction tensor. In the principal axis system (X, Y, Z) of the traceless electric field gradient tensor, the quadrupolar Hamiltonian can be written as^{13,24,25}

$$\hat{\mathcal{H}}_Q = \frac{1}{6}\hbar\omega_Q[3\hat{I}_Z^2 - I(I+1) + \eta(\hat{I}_X^2 - \hat{I}_Y^2)] \quad (15)$$

with $\eta = (V_{XX} - V_{YY})/V_{ZZ}$, where the quadrupolar frequency ω_Q is defined as

$$\omega_Q = \frac{3eQ}{2I(2I - 1)\hbar} V_{ZZ} \quad (16)$$

The definition of the quadrupolar frequency used here is consistent with the one employed by Cohen and Reif,²⁴ Abragam,⁴ and others.²⁶ There exist other definitions in the literature, however, where ω_Q differs by a factor of two compared with the definition used here.

The formulation in terms of spherical tensor operators is given in Section 5.4. The high field approximation will be discussed in Section 2.4. NMR spectra resulting from quadrupolar interactions are shown in Section 3.2. The physical origin of electric field gradients is outlined briefly in Section 5.3.

2.3 Spin–Spin Couplings

Direct as well as indirect spin–spin interactions^{14–16} both lead to a bilinear spin Hamiltonian. In a solid, a large number of nuclei are usually coupled to each other. The spin–spin coupling Hamiltonian can therefore be expressed in Cartesian form as

$$\hat{\mathcal{H}}_{II} = \hbar \sum_{j < k} \hat{\mathbf{I}}_j \cdot \mathbf{D}_{I_j I_k} \cdot \hat{\mathbf{I}}_k, \quad \hat{\mathcal{H}}_{IS} = \hbar \sum_{j,k} \hat{\mathbf{I}}_j \cdot \mathbf{D}_{I_j S_k} \cdot \hat{\mathbf{S}}_k \quad (17)$$

where the coupling occurs pairwise either between two homonuclear (I_j, I_k) or heteronuclear spins (I_j, S_k). The distinction between heteronuclear ($|\omega_{0I} - \omega_{0S}| \gg \omega_{IS}$) and homonuclear ($|\omega_{0I} - \omega_{0S}| \ll \omega_{IS}$) spins is based on their difference in resonance frequencies, where we define the spin–spin interaction frequency as $\omega_{IS} = \|\hat{\mathcal{H}}_{IS}\|/\hbar$. This distinction becomes important only when a magnetic field is applied, a case which is discussed in Sections 2.4 and 3.3. We shall use in the following sections the form $\hat{\mathcal{H}}_{II}$ for homonuclear spins exclusively and the form $\hat{\mathcal{H}}_{IS}$ for heteronuclear spins as well as for homonuclear spins if the corresponding expression applies to both. It should be kept in mind also that even between spins of the same type (e.g., two ^{13}C spins) the interaction can be of heteronuclear type if the difference frequency between the two ^{13}C spins is larger than their interaction frequency.

Let us first discuss the (direct) dipole–dipole interaction tensor between two nuclear spins I_j and S_k which can be expressed as

$$D_{\alpha\beta}^{(j,k)} = d_{jk}(\delta_{\alpha\beta} - 3e_\alpha e_\beta) \quad (18)$$

with $d_{jk} = (\mu_0/4\pi)\gamma_I\gamma_S\hbar/r_{jk}^3$ and $\text{Tr}\{D_{\alpha\beta}^{(j,k)}\} = 0$. This interaction depends only on the internuclear distance r_{jk} and the product of direction cosines $e_\alpha e_\beta$ ($\alpha, \beta = x, y, z$) of the distance vector with the (x, y, z) axes. The complete Hamiltonian can be represented in the form of the ‘dipolar alphabet’⁴ as

$$\hat{\mathcal{H}}_{IS} = \hbar d_{jk}(\hat{A} + \hat{B} + \hat{C} + \hat{D} + \hat{E} + \hat{F}) \quad (19)$$

with

$$\hat{A} = (1 - 3\cos^2\vartheta)\hat{I}_z\hat{S}_z \quad (19a)$$

$$\hat{B} = \frac{1}{2}(1 - 3\cos^2\vartheta)(\hat{I}_z\hat{S}_+ - \hat{I}_+ \hat{S}_z) \quad (19b)$$

$$\hat{C} = -\frac{3}{2}\sin\vartheta\cos\vartheta e^{-i\varphi}(\hat{I}_z\hat{S}_+ + \hat{I}_+ \hat{S}_z) \quad (19c)$$

$$\hat{D} = \hat{C}^* = -\frac{3}{2}\sin\vartheta\cos\vartheta e^{+i\varphi}(\hat{I}_z\hat{S}_- + \hat{I}_- \hat{S}_z) \quad (19d)$$

$$\hat{E} = -\frac{3}{4}\sin^2\vartheta e^{-i2\varphi}\hat{I}_+\hat{S}_+ \quad (19e)$$

$$\hat{F} = \hat{E}^* = -\frac{3}{4}\sin^2\vartheta e^{+i2\varphi}\hat{I}_-\hat{S}_- \quad (19f)$$

which, for a large number of homonuclear spins, can be summarized as

$$\hat{\mathcal{H}}_{II} = \hbar \sum_{j < k} d_{jk} \left[\hat{\mathbf{I}}_j \cdot \hat{\mathbf{I}}_k - 3 \frac{1}{r_{jk}^2} (\hat{\mathbf{I}}_j \cdot \mathbf{r}_{jk})(\hat{\mathbf{I}}_k \cdot \mathbf{r}_{jk}) \right] \quad (20)$$

The same expression applies to heteronuclear spins I_j and S_k where the sum is over j, k . Note that the dipole–dipole interaction tensor is both traceless and axially symmetric, i.e. it can be represented by a single quantity, namely the dipolar interaction strength d_{jk} .

If the spin–spin coupling is mediated by the surrounding electrons (indirect interaction) the representation in equation (18) applies, but with an interaction tensor $\{D_{\alpha\beta}\}$ that is neither traceless nor symmetric in the general case. All nine components of the interaction tensor must be considered. Although NMR spectra are only affected by the symmetric part of the interaction tensor, relaxation processes also involve the antisymmetric part. Relaxation will not be discussed here, however. In those cases where the trace of the indirect spin–spin interaction tensor is dominant (isotropic spin–spin coupling), we can express the corresponding Hamiltonian as

$$\hat{\mathcal{H}}_{II} = \hbar \sum_{j < k} J_{jk} \hat{\mathbf{I}}_j \cdot \hat{\mathbf{I}}_k \quad (21)$$

where $J_{jk} = \frac{1}{3} \text{Tr}\{D_{\alpha\beta}\}$. Often local orbital symmetry allows the indirect interaction to be axially symmetric. In those cases the anisotropic spin Hamiltonian has the same spin structure as the dipole–dipole Hamiltonian [equation (20)], with the only difference that the coupling constant d_{jk} is no longer purely geometric, but is a molecular orbital (MO) property. In the general case, the complete symmetric part of the indirect spin interaction tensor must be diagonalized, resulting in three principal values (D_{11}, D_{22}, D_{33}) and three principal axes. The spherical tensor form of spin–spin interactions is summarized in Section 5.4.

2.4 Spin Interactions in Large Magnetic Fields

NMR in solids is usually performed for two extreme cases, namely zero or large magnetic fields. In a zero magnetic field, those spin Hamiltonians that are independent of the magnetic field, such as the quadrupolar and spin–spin interaction

Hamiltonians, lead directly to resolved spectral lines at the difference frequency of their principal elements even in a powder sample. This is what makes zero field NMR/NQR so attractive.²⁷ However, information on the orientation of the principal elements is lost. In this section, we preferentially cover NMR in large magnetic fields where $\|\hat{\mathcal{H}}_0\| \gg \|\hat{\mathcal{H}}_{\text{int}}\|$, leading to a separation of the interaction Hamiltonian into secular ($\hat{\mathcal{H}}'_{\text{int}}$) and nonsecular terms ($\hat{\mathcal{H}}''_{\text{int}}$):

$$\hat{\mathcal{H}}_{\text{int}} = \hat{\mathcal{H}}'_{\text{int}} + \hat{\mathcal{H}}''_{\text{int}} \quad (22)$$

where $[\hat{\mathcal{H}}_0, \hat{\mathcal{H}}'_{\text{int}}] = 0$ and $[\hat{\mathcal{H}}_0, \hat{\mathcal{H}}''_{\text{int}}] \neq 0$. The physical reason for this separation is the rapid rotation of the spins by the introduction of the large magnetic field. Those terms of the interaction Hamiltonian that are time-independent under this rotation are ‘secular’, whereas all time dependent terms are called ‘non-secular’. This suggests transforming the density matrix $\hat{\rho}_l$ from the laboratory frame into the ‘rotating frame’, leading to the following equation of motion for the density matrix $\hat{\rho}$:

$$\frac{d}{dt}\hat{\rho} = -\frac{i}{\hbar}[\hat{\mathcal{H}}_{\text{int}}, \hat{\rho}] \quad (23)$$

where $\hat{\rho} = \exp[(i/\hbar)\hat{\mathcal{H}}_0(t)]\hat{\rho}_l(t)\exp[-(i/\hbar)\hat{\mathcal{H}}_0(t)]$ and $\tilde{\mathcal{H}}_{\text{int}}(t) = \exp[(i/\hbar)\hat{\mathcal{H}}_0(t)]\hat{\mathcal{H}}_{\text{int}}\exp[-(i/\hbar)\hat{\mathcal{H}}_0(t)]$. The secular part of the interaction Hamiltonian can now be extracted by the procedure

$$\hat{\mathcal{H}}'_{\text{int}} = \frac{1}{t_c} \int_0^{t_c} dt \tilde{\mathcal{H}}_{\text{int}}(t) \quad (24)$$

where $\omega_0 t_c = 2\pi$. In spherical tensor operator notation, terms of the type $T^{(l,m)} = \exp(\pm im\omega_0 t)$ appear in the time dependent Hamiltonian. When performing the time averaging [equation (26)], all terms vanish except those with $m = 0$, resulting in the general secular interaction Hamiltonian:

$$\hat{\mathcal{H}}'_{\text{int}} = \hbar(A^{(0,0)}\hat{T}^{(0,0)} + A^{(1,0)}\hat{T}^{(1,0)} + A^{(2,0)}\hat{T}^{(2,0)}) \quad (25)$$

where, however, the antisymmetric term $A^{(1,0)}\hat{T}^{(1,0)}$ is irrelevant for the spectrum, as mentioned earlier, and will be dropped. In order to be more specific, we shall now discuss secular parts of different interaction Hamiltonians in turn.

2.4.1 Heteronuclear

We begin with heteronuclear spin–spin interactions, where $\omega_{0I} \neq \omega_{0S}$, which leads to

$$\hat{\mathcal{H}}'_{IS} = \hbar D_{zz} \hat{I}_z \hat{S}_z \quad (26)$$

In the case of dipole–dipole interaction, the z component D_{zz} can be expressed as

$$D_{zz} = -\frac{\mu_0}{4\pi} \gamma_I \gamma_S \hbar r_{IS}^{-3} (3 \cos^2 \vartheta_{IS} - 1) \quad (27)$$

2.4.2 Homonuclear

The corresponding expression for homonuclear ($\omega_{0I} = \omega_{0S}$) spin–spin interaction is slightly more complicated and can be expressed in general by separating the isotropic part from the anisotropic part:

$$\hat{\mathcal{H}}'_{IS} = \hbar J \hat{I} \cdot \hat{S} + \hbar \frac{1}{2} (D_{zz} - J) (3 \hat{I}_z \hat{S}_z - \hat{I} \cdot \hat{S}) \quad (28)$$

with $J = \frac{1}{3} \text{Tr} \{D_{\alpha\beta}\}$. In the case of dipole–dipole interaction, the secular spin–spin interaction Hamiltonian reduces to

$$\hat{\mathcal{H}}'_{II} = \frac{\hbar}{2} \sum_{j < k} D_{zz}^{(j,k)} (3 \hat{I}_{jz} \hat{I}_{kz} - \hat{I}_j \cdot \hat{I}_k) \quad (29)$$

with $D_{zz}^{(j,k)} = -d_{jk} (3 \cos^2 \vartheta_{jk} - 1)$. The secular quadrupolar Hamiltonian assumes a similar form:

$$\hat{\mathcal{H}}'_Q = \frac{1}{6} \hbar \omega_{Qz} [3 \hat{I}_z^2 - I(I+1)] \quad (30)$$

with $\omega_{Qz} = [3eQ/2I(2I-1)\hbar]V_{zz}$ and $V_{zz} = V_{ZZ}[\frac{1}{2}(3 \cos^2 \beta - 1) + \frac{1}{2}\eta \sin^2 \beta \cos 2\alpha]$. Note that ω_{Qz} as defined here still contains the asymmetry parameter η and the full orientational dependence.

In the case of the shift Hamiltonian, the situation is rather simple, because only the z component survives the rotating-frame transformation

$$\hat{\mathcal{H}}'_S = -\hbar \gamma_I (K_{zz} - \sigma_{zz}) B_0 \hat{I}_z \quad (31)$$

leading to a relative shift in resonance frequency of $\delta_{zz} = K_{zz} - \sigma_{zz}$. In order to keep the treatment general, both shift contributions, namely the Knight shift and the chemical shift, are included here. For closed shell materials, only the chemical shift has to be considered. Note that the tensor character (anisotropy) of the shift interactions is still contained in the z component of the tensor. We shall see in the next section how this leads to an orientational dependence of the resonance line.

2.5 Transformation Properties of Spin Interactions

Transformations in NMR are usually rotations either in real space or spin space. The corresponding transformations are represented by unitary matrices. Rotations can be visualized either as rotations of an object like a vector or a tensor (matrix) or alternatively as a counter-rotation of the coordinate system. Both views lead to the same physical result. Here we express the rotation of a vector by $\mathbf{r}' = \mathbf{R}\mathbf{r}$, whereas a tensor (matrix) rotation is expressed as

$$\mathbf{A}' = \mathbf{R}\mathbf{A}\mathbf{R}^{-1} \quad (32)$$

where the rotation matrix $\mathbf{R}$ may be represented (in Cartesian notation) in terms of the direction cosines between the vectors $\mathbf{r}'$ and $\mathbf{r}$ as

$$\mathbf{R} = \{r_{ij}\} = \{\cos(\mathbf{r}', \mathbf{r})\} \quad (33)$$

with $\{r_{ij}\} = \{r_{ji}\}^{-1}$. The matrix multiplication

$$A'_{ij} = \sum_m A_{ml} r_{im} r_{jl} \quad (34)$$

results, where i, j represent the coordinates of the ‘new’ (i, j) frame, whereas (m, l) labels the coordinates of the ‘old’ frame. In the high-field approximation, the z component of the tensor governs the NMR spectrum. If the tensor $\mathbf{A}$ is given in the principal axis frame (X, Y, Z) by the principal elements (A_{XX}, A_{YY}, A_{ZZ}) the z component of the corresponding tensor in the laboratory (rotating) frame (x, y, z) is given by

$$A'_{zz} = \sum_m A_{mm} r_{zm}^2 = A_{XX} r_{zX}^2 + A_{YY} r_{zY}^2 + A_{ZZ} r_{zZ}^2 \quad (35)$$

which is readily expressed in terms of Euler angles (α, β) by

$$A'_{zz} = A_{XX} \cos^2 \alpha \sin^2 \beta + A_{YY} \sin^2 \alpha \sin^2 \beta + A_{ZZ} \cos^2 \beta \quad (36)$$

This is the typical form all anisotropic secular spin interactions assume, where the tensor elements $A_{\alpha\alpha}$ ($\alpha = X, Y, Z$) in equation (38) may be replaced by those of the shift, quadrupolar, or spin-spin interaction tensor. The orientational dependence of the spin interaction as represented in equation (38) determines the orientational dependence of the lineshift, as well as the quadrupolar and dipolar broadening and splitting.

When discussing rotations, we use the sign convention and the Euler angle definition of Rose,²⁸ where a counterclockwise rotation is defined as positive. Such a rotation by Euler angles $(\alpha\beta\gamma)$ can be expressed as a rotation about the z axis by the angle α followed by a rotation about the new y' axis by the angle β , and the final rotation about the new z'' axis by the angle γ , which can be summarized as

$$R(\alpha\beta\gamma) = R_{z''}(\gamma)R_{y'}(\beta)R_z(\alpha) \quad (37)$$

In terms of the original axes, the same rotation can be written as

$$R(\alpha\beta\gamma) = R_z(\alpha)R_y(\beta)R_z(\gamma) \quad (38)$$

In order to provide an example in spin space, we consider the rotation operator about the x axis by an angle α :

$$\begin{aligned} \exp(-i\alpha\hat{I}_x) &= \exp(i\frac{1}{2}\pi\hat{I}_z)\exp(-i\alpha\hat{I}_y)\exp(-i\frac{1}{2}\pi\hat{I}_z) \\ &= R(-\frac{1}{2}\pi\alpha\frac{1}{2}\pi) \end{aligned} \quad (39)$$

The application of these rotation operators to spin operators follows simple transformation rules. The example given here can readily be extended to the operator set $(\hat{I}_x, \hat{I}_y, \hat{I}_z)$. The following example follows directly from the vector picture of spin operators:

$$\exp(-i\alpha\hat{I}_z)\hat{I}_x\exp(i\alpha\hat{I}_z) = \hat{I}_x \cos \alpha + \hat{I}_y \sin \alpha \quad (40)$$

It can readily be extended to other rotations by applying classical vector rotation rules. Note, however, that these transformations are quantum mechanically exact and not a classical analogue. Moreover, they apply to any spin operator independent of the spin quantum number.

Since irreducible spherical tensor operators are specially designed to have convenient rotational properties, we can express rotations of these in the compact form^{9,10,20,21,28,29}

$$\hat{T}^{(l,m)} = R(\alpha\beta\gamma)\hat{T}^{(l,m)}R(\alpha\beta\gamma)^{-1} = \sum_{n=-l}^{+l} \hat{T}^{(l,n)}D_{nm}^l(\alpha\beta\gamma) \quad (41)$$

by using the Wigner rotation matrix

$$D_{nm}^l(\alpha\beta\gamma) = e^{-in\alpha}d_{nm}^l(\beta)e^{-im\gamma} \quad (42)$$

The reduced rotation matrices $d_{nm}^l(\beta)$ are real and are listed for different values of l in Section 5.5. These transformation properties will be applied in Section 4 in order to discuss rotational properties of NMR spectra in solids.

3 NMR SPECTRA

NMR spectra can be recorded in a number of different ways. Several articles in the Encyclopedia deal with special techniques, and there are textbooks which discuss, for example, special high-resolution techniques in solid state NMR spectroscopy. In this article I restrict myself to 'basic spectra' which are obtained by, for example, Fourier transformation of the free induction decay after $\frac{1}{2}\pi$ pulse excitation. The time evolution of this FID is governed by the internal spin interactions discussed in Section 2, and can be expressed as

$$G(t) = \frac{\text{Tr}\{\hat{I}_+ e^{-i\hat{\mathcal{H}}t} \rho(0) e^{i\hat{\mathcal{H}}t}\}}{\text{Tr}\{\hat{I}_+^2\}} \quad (43)$$

where $\rho(0)$ represents the density matrix at $t = 0$ directly after the $\frac{1}{2}\pi$ pulse and $\hat{\mathcal{H}}$ is the time-independent effective Hamiltonian governing the spin evolution, and $\hat{I}_+ = \hat{I}_x + i\hat{I}_y$ is the 'detection operator', which includes the two orthogonal (x, y) detection channels. The Hamiltonian used in equation (45) must be considered an effective Hamiltonian depending on the type of pulse (or multiple pulse) experiment performed. In the simple case where the Hamiltonian is diagonal in the Zeeman representation, the trace operation is conveniently expressed by

$$\begin{aligned} G(t) &= \frac{1}{\text{Tr}\{\hat{I}_+^2\}} \sum_{m=-l}^{l-1} \sqrt{I(I+1) - m(m+1)} \rho_{m,m+1} \\ &\times \exp[-i(H_m - H_{m+1})t] \end{aligned} \quad (44)$$

where $H_m = \langle m | \hat{\mathcal{H}} / \hbar | m \rangle$ and $\rho_{m,m+1} = \langle m | \hat{\rho}(0) | m+1 \rangle$. This case is realized in the high-field approximation for all interactions discussed here besides the homonuclear spin-spin interaction. After Fourier transformation, the spectrum

$$\begin{aligned} F(\omega) &= \frac{1}{\text{Tr}\{\hat{I}_+^2\}} \sum_{m=-l}^{l-1} \sqrt{I(I+1) - m(m+1)} \rho_{m,m+1} \\ &\times \delta[\omega - (H_{m+1} - H_m)] \end{aligned} \quad (45)$$

results. This corresponds to line spectra consisting of delta functions at the frequencies

$$\omega_{m,m+1} = H_m - H_{m+1} \quad (46a)$$

with intensities

$$I_{m,m+1} = \frac{\sqrt{I(I+1) - m(m+1)} \rho_{m,m+1}}{\frac{1}{3}I(I+1)(2I+1)} \quad (46b)$$

In the general case the Hamiltonian must be diagonalized and the eigenstates must be used in the evaluation of the trace. In solids, the eigenvalues H_m and the matrix elements $\rho_{m,m+1}$ usually depend on the orientation of the magnetic field with respect to the principal axes of the interaction tensor (see Section 4).

3.1 Lineshift Spectra

Shift spectra are usually recorded in large magnetic fields, i.e., the high-field approximation applies (see Section 2.4). In a single crystal, the NMR spectrum consists of a single line for every nuclear site. Owing to symmetry, several nuclear

sites in a molecule or in the unit cell can be magnetically equivalent, i.e., they give rise to a single line. The line is shifted with respect to the nuclear Larmor frequency and appears at frequency $\omega = \omega_0 + \delta$. In practice, a reference sample is used, to which the observed shift is related by $\delta_{\text{obs}} = \delta - \delta_{\text{ref}}$. In a solid with low nuclear site symmetry, this shift depends on the orientation of the magnetic field with respect to the principal axis system of the shift tensor. By using a goniometer as discussed in detail in Section 4.1, so-called rotation plots of the orientation-dependent shifts are obtained, from which the shift tensor can be determined. An example of a shift tensor determination from single crystal rotation plots, in which multiple pulse line-narrowing techniques were used in order to obtain resolved spectral lines, was presented by Griffin et al.³⁰

In Figure 2 different NMR line spectra of ^{13}C , obtained from a single crystal of the organic conductor (fluoranthenyl) $_2\text{PF}_6$, are plotted for different orientations of the magnetic field.³¹ Note the variation of the lineshifts with the orientation. The functional form of these ‘rotation plots’ will be discussed in Section 4.1. Besides the pronounced orientational dependence shown in Figure 2, it is of importance that the lineshifts are caused by both the chemical shift and the Knight shift tensors, which are additive.

In a powder sample the orientation of the principal axis system with respect to the magnetic field occurs with

Figure 2 Carbon-13 NMR single crystal spectra of the 1D organic conductor (fluoranthenyl) $_2\text{PF}_6$ for different orientations of the magnetic field perpendicular to the stacking axis. (Reproduced by permission of The American Physical Society from D. Köngeter and M. Mehring, *Phys. Rev. B*, 1989, **39**, 6361)

Figure 3 Calculated powder spectra of anisotropic spin interactions, where the dotted lines correspond to unbroadened (ideal) spectra, and the spectra indicated by thick lines are additionally broadened in order to mimic experimental spectra. Top: axially symmetric shift tensor with $\nu_{11} = \nu_{22} = -50$ a.u. and $\nu_{33} = 100$ a.u. Middle: nonaxially symmetric shift tensor with $\nu_{11} = -70$ a.u., $\nu_{22} = -30$ a.u. and $\nu_{33} = 100$ a.u. Bottom: Pake pattern spectra³⁷ either due to a spin $I = 1$ axially symmetric quadrupole interaction or dipole–dipole coupling of two spin-1/2 nuclei. The maximum coupling strength (ν_{33} , $\mathbf{B}_0 \parallel$ unique axis) is 100 a.u.

probability $P(\Omega)$, where Ω is the solid angle ($\alpha\beta$). The ‘powder lineshape’

$$I(\omega) = \int d\Omega P(\Omega) I(\omega, \Omega) \quad (47)$$

results where $d\Omega = \sin \beta d\beta d\alpha$ and $I(\omega, \Omega)$ is the NMR spectrum for orientation Ω . For an isotropic powder $P(\Omega) = \frac{1}{4\pi}$. Typical examples of powder spectra of axially and nonaxially symmetric shift tensors are shown in Figure 3 (top and middle). Note the edges and the center singularities, which are characteristic features of these spectra and from which the principal elements of the shift tensor can be determined.

In practice it is, however, more appropriate to make a computer fit of the experimental spectra to the calculated lineshape, which can be expressed as

$$I(\omega) = \frac{K(m)}{\pi \sqrt{(\omega - \omega_{11})(\omega_{33} - \omega_{22})}} \quad \text{for } \omega_{33} \geq \omega > \omega_{22} \quad (48)$$

Figure 4 Experimental ^{19}F powder spectrum of fluoranil ($\text{C}_6\text{F}_4\text{O}_2$ at 300 K). The nonaxially symmetric shift tensor elements σ_{11} , σ_{22} , and σ_{33} are indicated. The powder spectrum corresponds to the theoretical spectrum shown in Figure 3 (middle). (Reproduced by permission of The American Physical Society from M. Mehring, R. G. Griffin, and J. S. Waugh, *J. Chem. Phys.* 1971, **59**, 746)

with $m = (\omega_{22} - \omega_{11})(\omega_{33} - \omega)/(\omega_{33} - \omega_{22})(\omega - \omega_{11})$,

$$I(\omega) = \frac{K(m)}{\pi \sqrt{(\omega_{33} - \omega)(\omega_{22} - \omega_{11})}} \quad \text{for } \omega_{22} \geq \omega_{11} \quad (49)$$

with $m = (\omega - \omega_{11})(\omega_{33} - \omega_{22})/(\omega_{33} - \omega)(\omega_{22} - \omega_{11})$, and $I(\omega) = 0$ for $\omega > \omega_{33}$ and $\omega < \omega_{11}$. $K(m)$ is the complete elliptic integral of the first kind:

$$K(m) = \int_0^{\pi/2} d\varphi (1 - m \sin^2 \varphi)^{-1/2} \quad (50)$$

In order to compare this lineshape with the experimentally observed lineshape, it must be convoluted with a line-broadening function. In practice, Lorentzian or Gaussian functions are used as line-broadening functions. In Figure 3, a Lorentzian broadening function was applied, leading to a rounding off of the edges and singularities (thick lines). In order to speed up the numerical calculation of powder spectra, Aldermann et al.³² have proposed a fast algorithm.

The type of powder pattern discussed here was first observed by Bloembergen and Rowland³³ in metallic thallium, where the shift anisotropy is larger than any other interaction. In ordinary solids, this is usually not the case because of dominant dipolar broadenings. With the advent of high-resolution NMR techniques, chemical shift powder patterns became observable in many materials where without these methods only structureless broad lines appeared in the NMR spectra.⁸ An early example of such a resolution enhanced powder spectrum is shown in Figure 4.

Resolution was enhanced in Figure 4 by applying a multiple pulse experiment of the WAHUA type, which eliminates the dipole–dipole interaction among the ^{19}F spins on the average.³⁴ A summary of experimentally determined chemical shift tensors of different nuclei can be found in the literature,¹⁰ in particular in a review on ^{13}C chemical shift tensors by Duncan.³⁵

3.2 Quadrupole Spectra

In cubic solids, the electric field gradient vanishes because of symmetry. The quadrupolar interaction has nevertheless

Figure 5 Powder spectra caused by first-order quadrupole interaction (central transition omitted) for nuclear spin $I = 3/2$ (top) and $I = 5/2$ (bottom) for two different values of the asymmetry parameter $\eta = 0.1$ and 0.6 . (Reproduced by permission of Springer-Verlag from D. Freude and J. Haase, in *NMR Basic Principles and Progress*, eds. P. Diehl, E. Fluch, and R. Kosfeld, Springer-Verlag, Berlin, 1993, Vol. 29, p. 25)

been observed in cubic solids, caused by point defects and dislocations.³⁶ Surprisingly, it was found that for point defects a Lorentzian lineshape (exponential FID) results, which is usually taken as evidence for homogeneous broadening.³⁶ Here we restrict ourselves to solids where the local symmetry is low enough to observe quadrupolar splittings directly. In zero magnetic field, the transition frequencies between the different eigenstates of the quadrupole Hamiltonian do not depend on the orientation of the electric field gradient tensor. Therefore, narrow lines are observed even in powder samples. This has been developed into a special kind of ‘zero field spectroscopy’, covered separately in this Encyclopedia.

In large magnetic fields only the secular part of the Hamiltonian contributes to the spectrum (see Section 2.4). In the case of the quadrupolar interaction, this results in first-order quadrupolar spectra with transition frequencies

$$\omega_{m,m+1} = \omega_0 + \omega_Q \left[\frac{1}{2} (3 \cos^2 \beta - 1) + \frac{1}{2} \eta \sin^2 \beta \cos 2\alpha \right] (m + \frac{1}{2}) \quad (51)$$

Because of the spin symmetry, the spectra correspond to pairs of lines symmetrical about ω_0 where the additional line in the center (at ω_0) appears for half-integer spins. The corresponding intensities follow from equation (49). The simplest situation is encountered for a nuclear spin $I = 1$ (e.g., ^2D), which results in a doublet of lines separated by the quadrupolar frequency. The corresponding powder spectrum depends on the symmetry of the electric field gradient. If the electric field gradient is axially symmetric, the typical ‘Pake pattern’³⁷ [Figure 3 (bottom)] results, which consists of the sum of the axially symmetric shift pattern [Figure 3 (top)] and its mirror image symmetrical to zero frequency. For a nonaxially symmetric field gradient, the original and the mirror image of the nonaxially symmetric shift pattern [Figure 3 (middle)] must be added. For half-integer nuclear spins, the procedure is similar, but more complicated spectra result. Some examples are shown in Figure 5.

If the first-order approximation is no longer valid because of an increased quadrupole interaction, it is best to perform a

Figure 6 Powder spectra of the central transition ($-1/2 \rightarrow 1/2$) caused by the second-order quadrupole interaction of arbitrary half-integer spin nuclei for different values of the asymmetry parameter η . (Reproduced by permission of Springer-Verlag from D. Freude and J. Haase in NMR Basic Principles and Progress, eds. P. Diehl, E. Fluch, and R. Kosfeld, Springer-Verlag, Berlin, 1993, Vol. 29, p. 27)

numerical diagonalization of the Hamiltonian and to calculate the corresponding spectrum. Although this procedure is numerically rather trivial, second-order quadrupolar transition frequencies have been calculated in the past in order to cope with this situation. For completeness, we include here the transition frequency for the central transition ($-\frac{1}{2} \rightarrow \frac{1}{2}$) of half-integer spins

$$\omega_{-1/2,1/2} = -\frac{\omega_Q^2}{6\omega_0} [I(I+1) - \frac{3}{4}] \times [A(\alpha, \eta) \cos^4 \beta + B(\alpha, \eta) \cos^2 \beta + C(\alpha, \eta)] \quad (52)$$

where

$$A = -\frac{27}{8} - \frac{9}{4}\eta \cos 2\alpha - \frac{3}{8}\eta^2 \cos^2 2\alpha \quad (52a)$$

$$B = \frac{15}{4} - \frac{1}{2}\eta^2 + 2\eta \cos 2\alpha + \frac{3}{4}\eta^2 \cos^2 2\alpha \quad (52b)$$

$$C = -\frac{3}{8} + \frac{1}{3}\eta^2 + \frac{1}{4}\eta \cos 2\alpha - \frac{3}{8}\eta^2 \cos^2 2\alpha \quad (52c)$$

Equations (52)–(52c) were first derived by Narita et al.³⁸ and applied to the calculation of the second-order powder pattern of the central transition for arbitrary half-integer spin- $\frac{1}{2}$ nuclei. Powder spectra of the central transition in half-integer spin systems are shown in Figure 6 for different values of η . Further details about quadrupolar spectra can be found in the recent review by Freude and Haase.²⁶

3.3 Spin–Spin Splittings

Spin–spin couplings in the high-field approximation produce line splittings, as is evident from the corresponding Hamiltonian (see Section 2.4). We must distinguish two different cases, namely

1. heteronuclear interactions: $|\omega_{0I} - \omega_{0S}| \gg |\omega_{IS}|$;
2. homonuclear interactions: $|\omega_{0I} - \omega_{0S}| \ll |\omega_{IS}|$.

noindent ω_{IS} is the corresponding interaction frequency between spin I and spin S . These conditions do not require, however, that I and S be different types of nuclear spins, merely that their resonance frequency difference with respect to the interaction frequency determines whether they must be considered as homo- or heteronuclear.

3.3.1 Heteronuclear Interaction

The symmetric part of the secular interaction Hamiltonian can be expressed in this case as

$$\hat{\mathcal{H}}'_{IS} = \hbar \sum_{j,k} D_{zz}^{(j,k)} \hat{I}_{zj} \hat{S}_{zk} \quad (53)$$

as was shown in Section 2.4. Let us assume that we are interested in the spectrum of the I spins. Under the assumption that the S – S spin coupling is much weaker than the I – S coupling, an exact expression can be obtained for the FID of the I_j spin coupled to N_s S spins,¹⁰

$$G_{IS}(t) = \prod_k \frac{\text{Tr}[\cos(D_{zz}^{(j,k)} t) \hat{S}_{zk}]}{(2S+1)^{N_s}} \quad (54)$$

which takes the following special forms for some representative values of S :

$$S = \frac{1}{2}: \quad G_{IS}(t) = \prod_k \cos(\frac{1}{2} D_{zz}^{(j,k)} t) \quad (54a)$$

$$S = 1: \quad G_{IS}(t) = \prod_k \frac{1}{3} [1 + 2 \cos(D_{zz}^{(j,k)} t)] \quad (54b)$$

$$S = \frac{3}{2}: \quad G_{IS}(t) = \prod_k \frac{1}{2} [\cos(\frac{1}{2} D_{zz}^{(j,k)} t) + \cos(\frac{3}{2} D_{zz}^{(j,k)} t)] \quad (54c)$$

The corresponding spectra are readily obtained after Fourier transformation. Note that $D_{zz}^{(j,k)}$ does include the isotropic interaction J . In the case of a single spin $S = \frac{1}{2}$ coupled to a spin I , a pair of lines at frequencies

$$\omega = \omega_0 \pm d_{IS} \frac{1}{2} (1 - 3 \cos^2 \vartheta_{IS}) \quad (55)$$

with $d_{IS} = (\mu_0/4\pi) \gamma_I \gamma_S \hbar / r_{IS}^3$ results. In the case of a powder sample, an average over all angles ϑ_{IS} must be performed, leading to a ‘Pake pattern’ as displayed in Figure 3 (bottom), where the outermost edges appear at $\omega_0 \pm d_{IS}$.

3.3.2 Homonuclear Interaction

In this case, it is convenient to separate the isotropic from the anisotropic part, leading to

$$\hat{\mathcal{H}}'_{II} = \frac{1}{2} \hbar J_{jk} \hat{I}_j \cdot \hat{I}_k + \hbar (D_{zz}^{(j,k)} - J_{jk}) (3 \hat{I}_{jz} \hat{I}_{kz} - \hat{I}_j \cdot \hat{I}_k) \quad (56)$$

with $J_{jk} = \frac{1}{3} \text{Tr} \{D_{\alpha\beta}^{(j,k)}\}$ for the spin–spin coupling between two nuclear spins I_j and I_k . Unfortunately, this Hamiltonian is no longer diagonal, and thus a diagonalization procedure has to be applied for the calculation of the FID and the corresponding spectrum. In the case of the dipole–dipole interaction the

isotropic part vanishes, and for two coupled spin- $\frac{1}{2}$ nuclei a pair of lines results at frequencies

$$\omega = \omega_0 \pm \frac{3}{2}d_{II}\frac{1}{2}(1 - 3\cos^2\vartheta_{II}) \quad (57)$$

with $d_{II} = (\mu_0/4\pi)\gamma_I^2\hbar/r_{II}^3$. For a powder sample, the typical ‘Pake pattern’ again results [see Figure 3 (bottom)]. In contrast to the heteronuclear case, here the outermost edges appear at $\omega_0 \pm 0.75d_{II}$.

3.4 The Multispin Lineshape Problem

The multispin lineshape problem for heteronuclear interactions has been discussed in the previous section. Here we consider N homonuclear spins of type I . The truncated (high field) interaction Hamiltonian can be expressed as

$$\hat{\mathcal{H}}'_{II} = \hbar \sum_{j < k} [J_{j,k} \hat{\mathbf{I}}_j \cdot \hat{\mathbf{I}}_k + \frac{1}{2}(D_{zz}^{(j,k)} - J_{j,k})(3\hat{I}_{jz}\hat{I}_{kz} - \hat{\mathbf{I}}_j \cdot \hat{\mathbf{I}}_k)] \quad (58)$$

For a limited number of spins, a numerical diagonalization is feasible. However, already for 10 spin- $\frac{1}{2}$ nuclei, a 1024×1024 Hamiltonian matrix must be diagonalized. For much larger spin clusters, supercomputer power is needed, and reaches the current computational limit very quickly. In practical cases, one therefore has to resort to approximation schemes. The most obvious procedure is Van Vleck’s moment expansion,³⁹ which is in fact exact in the case where an infinite number of moments is taken into account. It follows from the symmetry of the interaction Hamiltonian that only even order moments must be considered. The FID can in this case be expressed as

$$G(t) = 1 - \frac{1}{2!}M_2t^2 + \frac{1}{4!}M_4t^4 - \dots + \dots \quad (59)$$

where higher order terms become exceedingly difficult to calculate.⁴⁰ In more or less evenly distributed nuclear spins in a solid, the observed lineshape is often Gaussian, as is the FID. In this case, a very good approximation is

$$G(t) = \exp(-\frac{1}{2}M_2t^2) \quad (60)$$

with the corresponding lineshape

$$F(\omega) = \frac{1}{\sqrt{2\pi M_2}} \exp\left(-\frac{\omega^2}{2M_2}\right) \quad (61)$$

The full width at half-height (FWHH) of this lineshape is given by $\Delta\nu = \sqrt{2\ln 2}M_2/\pi$. The calculation of the second and fourth moments can be performed rigorously, and results in⁴

$$M_2 = \frac{3}{4}I(I+1)p \sum_{j < k} (D_{zz}^{(j,k)})^2 \quad (62)$$

$$\begin{aligned} M_4 = & \left[\frac{3}{4}I(I+1)\right]^2 \left\{ 3 \left[p \sum_k (D_{zz}^{(j,k)})^2 \right]^2 \right. \\ & - \frac{1}{3N} p^2 \sum_{j,k,m \neq} (D_{zz}^{(j,k)})^2 (D_{zz}^{(j,m)} - D_{zz}^{(k,m)})^2 \\ & \left. - \frac{1}{5} p \sum_k (D_{zz}^{(j,k)})^4 \left[8 + \frac{3}{2I(I+1)} \right] \right\} \quad (63) \end{aligned}$$

where $\sum_{j,k,m \neq}$ means that all indices must be unequal. Note that a population factor p was introduced in equations (67) and (68), which takes the isotopic abundance p of nuclear spins I into account, where $p = 1$ for 100% abundance. The summation is performed over all possible sites of spin I . Instead of calculating higher order terms a practical approach is to assume special functional forms of the FID, whose second and fourth moments are set to the values calculated according to equations (67) and (68). Prompted by the idea of Abragam, who used a truncated Lorentzian in order to obtain a linewidth expression based only on the second and fourth moments, an attempt was made to derive a simple linewidth expression by applying a memory function approach, which resulted in the expression¹⁰

$$\Delta\nu = \sqrt{\frac{M_2}{2\pi(\mu - 1.87)}} \quad (64)$$

where $\mu = M_4/M_2^2$ is a dimensionless parameter, which equals 3 in the case of a Gaussian function, and which assumes large values for $\mu \gg 3$ if the character of the lineshape is more Lorentzian. Equation (69) is valid to a good approximation also in the intermediate regime. Note that in a diluted spin system ($p \ll 1$), the moment ratio μ becomes large according to equations (67) and (68), resulting in a narrow line of more Lorentzian character as for $p = 1$.

4 ROTATIONS

Rotation operations are performed by unitary transformations applied to real space tensors or to spin space tensor operators as introduced in Section 2.5. We shall apply the rules quoted there in order to work out the corresponding frequency shifts or splittings observed in NMR spectra in solids. The most general scheme of transformations necessary for obtaining the spatial tensor (operator) $\mathbf{A}_1$ in the laboratory frame ($x y z$) is

$$\begin{array}{ccc} \mathbf{A}_p & \xrightarrow{\hat{R}_p(\alpha'\beta'\gamma')} & \mathbf{A}_c \\ (XYZ) & & (x_c y_c z_c) \\ \text{principal axis system} & & \text{crystal frame} \\ & \xrightarrow{\hat{R}_c(\alpha\beta\gamma)} & \mathbf{A}_g \\ & & (x_g y_g z_g) \\ & & \text{goniometer frame} \\ & \xrightarrow{\hat{R}_g(\varphi\theta\psi)} & \mathbf{A}_1 \\ & & (x y z) \\ & & \text{laboratory frame} \end{array} \quad (65)$$

We start from the principal axis system, i.e., the frame in which the symmetric part of the tensor is diagonal, and distinguish different reference frames such as the *crystal frame*, the *goniometer frame*, and the *laboratory frame*. The goniometer frame is a synonym for any frame with a unique axis about which rotations (flippings) can occur. This includes a real goniometer as well as a spinner and a molecular rotation frame. Each type of rotation will be discussed in turn in the following sections.

There may not always be a crystal frame (as in glasses and polymers). In this case, the two transformations $\hat{R}_p$ and $\hat{R}_c$ can be combined into a single one. The total transformation required when transforming from the principal axis system to the laboratory frame can be written as the product of single step transformations:

Table 1 Relation Between the Parameters A , C , S in Equation 78 and the Cartesian Chemical Shift Tensor Elements for Three Different Orthogonal Settings of the Goniometer Axis with Respect to the Crystal Axes

	x axis: $\alpha = \gamma = 0, \beta = \frac{1}{2}\pi$	y axis: $\alpha = \frac{1}{2}\pi, \beta = \frac{1}{2}\pi, \gamma = \frac{1}{2}\pi$	z axis: $\alpha = \beta = \gamma = 0$
A	$\frac{1}{2}(\sigma_{zz} + \sigma_{yy})$	$\frac{1}{2}(\sigma_{xx} + \sigma_{zz})$	$\frac{1}{2}(\sigma_{xx} + \sigma_{yy})$
S	$-\sigma_{yz}$	σ_{xz}	σ_{xy}
C	$\frac{1}{2}(\sigma_{zz} - \sigma_{yy})$	$\frac{1}{2}(\sigma_{zz} - \sigma_{xx})$	$\frac{1}{2}(\sigma_{xx} - \sigma_{yy})$

$$\hat{R}_{\text{total}} = \hat{R}_g(\varphi\vartheta\psi)\hat{R}_c(\alpha\beta\gamma)\hat{R}_p(\alpha'\beta'\gamma') \quad (66)$$

In terms of Wigner rotation matrices, the total transformation leads to

$$A_1^{(k,q)} = \sum_{m,n,r=-l}^{+k} A_p^{(k,m)} D_{mn}^k(\alpha'\beta'\gamma') D_{nr}^k(\alpha\beta\gamma) D_{rq}^k(\varphi\vartheta\psi) \quad (67)$$

Very often, rotation operations can be contracted into a single operation, and only a subset of the total transformation is required. This will be applied partially in the next sections.

4.1 Sample Rotation

Single crystal investigations were performed in the early days of NMR.⁴¹ They can reveal the complete symmetric part of the shift tensor if performed properly. Consider a sample that is rotated about a specific axis which might be tilted by an angle ϑ with respect to the static magnetic field. A set of Euler angles $(\varphi\vartheta\psi)$ is appropriate to describe these rotations. Spectra taken in the laboratory frame are proportional to $A_1^{(0,0)}$ and $A_1^{(2,0)}$, where $A_1^{(0,0)}$ represents the isotropic part and is therefore invariant under rotation, whereas the anisotropic part $A_1^{(2,0)}$ is transformed according to

$$\begin{array}{ccc} \mathbf{A}_g & \xrightarrow{R(\varphi\vartheta\psi)} & \mathbf{A}_l \\ (x_g y_g z_g) & & (x y z) \\ \text{goniometer frame} & & \text{laboratory frame} \end{array} \quad (68)$$

which leads to

$$A_1^{(2,0)} = \sum_{m=-2}^{+2} A_g^{(2,m)} D_{m0}^2(\varphi\vartheta\psi) \quad (69)$$

where $\mathbf{A}_g$ represents the tensor in the goniometer frame. Note that the angle ψ becomes irrelevant in this case, and for a fixed tilt angle ϑ only the 'rotation angle' φ is varied from one goniometer setting to the next. In the most general case, $A_1^{(2,0)}$ can be expressed as

$$A_1^{(2,0)} = a_0 + a_1 e^{-i\varphi} + a_{-1} e^{i\varphi} + a_2 e^{-i2\varphi} + a_{-2} e^{i2\varphi} \quad (70)$$

with $a_m = A_g^{(2,m)} d_{m0}^2(\vartheta)$, which leads to the following φ dependence of the z component of the chemical shift tensor:

$$\sigma_{zz}(\varphi) = A + S_1 \sin \varphi + C_1 \cos \varphi + S_2 \sin 2\varphi + C_2 \cos 2\varphi \quad (71)$$

where $A = \sigma_{\text{iso}} + \sqrt{\frac{2}{3}} a_0$ and

$$S_1 = i\sqrt{\frac{2}{3}}(a_{-1} - a_1), \quad C_1 = \sqrt{\frac{2}{3}}(a_{-1} + a_1) \quad (71a)$$

$$S_2 = i\sqrt{\frac{2}{3}}(a_{-2} - a_2), \quad C_2 = \sqrt{\frac{2}{3}}(a_{-2} + a_2) \quad (71b)$$

Related expressions can be obtained for the dipolar and quadrupolar splittings. Since the a_m contain a combination of the six tensor elements of the symmetric part of the shift tensor all symmetric tensor elements can be determined in a single rotation plot if σ_{iso} is known. This requires, however, that the tilt angle ϑ is chosen appropriately in order to avoid degeneracies. It is more common to choose $\vartheta = \frac{1}{2}\pi$, in which case equation (76) reduces to

$$\sigma_{zz}(\varphi) = A + S \sin 2\varphi + C \cos 2\varphi \quad (72)$$

with $A = \sigma_{\text{iso}} - \sqrt{\frac{1}{6}} A_g^{(2,0)}$, $S = \frac{1}{2}i(A_g^{(2,-2)} - A_g^{(2,2)})$, and $C = (A_g^{(2,-2)} + A_g^{(2,2)})$, where the relation between spherical tensor components $A_g^{(2,m)}$ and the Cartesian tensor elements of the shift tensor in the goniometer frame are given in Table 1. In order to determine the complete shift tensor in the crystal frame, usually three different orthogonal settings of the crystal with respect to the goniometer are required. Let us label the corresponding Euler angles $(\alpha\beta\gamma)$ as outlined in the transformation scheme, equation (70), at the beginning of this section. Table 1 summarizes the parameters A , S , and C in terms of the Cartesian chemical shift tensor elements, where only the symmetric part of the shift tensor ($\sigma_{jk} = \sigma_{kj}$) is considered. In the case of quadrupolar interactions the corresponding field gradient tensor elements, and in the case of spin-spin interactions the corresponding spin-spin coupling tensor elements, must be inserted.

An experimental example of rotation plots according to equation (78) has been shown in Figure 2. Fitting the φ dependence of the observed line shifts to equation (78) allows one to determine the parameter set (A, S, C) . If this procedure is followed for the three orthogonal axes (x, y, z) of the crystal setting with respect to the goniometer z axis, the column vector $\mathbf{A} = (A_x, S_x, C_x, A_y, S_y, C_y, A_z, S_z, C_z)$ results, which can be related according to Table 1 to the column vector $\mathbf{s} = (\sigma_{xx}, \sigma_{xy}, \sigma_{xz}, \sigma_{yy}, \sigma_{yz}, \sigma_{zz})$ or to the corresponding tensor elements of other types of interactions. Although the chemical shift tensor elements can be directly determined from the different A_k, S_k, C_k with $k = x, y, z$ according to Table 1, it is more practical to determine the elements of the vector $\mathbf{s}$ from the following set of linear equations:

$$\mathbf{s} = \mathbf{M}\mathbf{A} \quad (73)$$

where the matrix

$$\mathbf{M} = \begin{pmatrix} 0 & 0 & 0 & 0.5 & 0 & -0.5 & 0.5 & 0 & 0.5 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0.5 & 0 & -0.5 & 0 & 0 & 0 & 0.5 & 0 & -0.5 \\ 0 & -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0.5 & 0 & 0.5 & 0.5 & 0 & 0.5 & 0 & 0 & 0 \end{pmatrix} \quad (74)$$

follows directly from Table 1. If other crystal settings are used, the matrix $\mathbf{M}$ is changed. The overdetermination of the linear equations can be utilized in order to correct for misalignment

of the crystal and other experimental errors. As a result of the whole procedure, the symmetric part of the chemical shift tensor is obtained in the crystal axis frame. As a final step, a diagonalization of the symmetric part of the chemical shift tensor is performed, which leads to the principal elements and the principal axes of the chemical shift tensor in the crystal axis frame.

4.2 Sample Spinning

Whereas sample rotation as discussed in the preceding section is performed by rotating the goniometer axis in steps while taking spectra after each step, sample spinning is performed continuously where the spinner axis, which may be tilted by an arbitrary angle ϑ with respect to the magnetic field axis, is rotated with angular frequency ω_R . Andrew et al.⁴² and Lowe⁴³ proposed that considerable narrowing of NMR lines could be achieved by sufficiently fast rotation of a sample, where the spinner axis is tilted with respect to the magnetic field axis. Schaefer et al.⁴⁴ later applied this technique to polymers. At this point, the reader is referred to **Magic Angle Spinning**. Here we restrict ourselves to the tensor character of spin interactions under rotation. In order to analyze the spectra, we assume that the angle φ in equations (76) and (78) is replaced by $\varphi = \omega_R t$, which results in a time-dependent frequency

$$\begin{aligned}\omega(t) &= \sigma_{zz}(t)\omega_0 \\ &= \omega_0 \left[\sigma_{\text{iso}} + \sqrt{\frac{2}{3}}(a_0 + a_1 e^{-i\omega_R t} + a_{-1} e^{i\omega_R t} \right. \\ &\quad \left. + a_2 e^{-i2\omega_R t} + a_{-2} e^{i2\omega_R t}) \right]\end{aligned}\quad (75)$$

which generates oscillatory behavior of the FID and leads to sidebands in the spectrum. Let us first consider the average frequency $\bar{\omega}$, which corresponds to neglecting the sidebands:

$$\bar{\omega} = \omega_0 [\sigma_{\text{iso}} + \frac{1}{2}(3 \cos^2 \vartheta - 1)(\sigma_{zz} - \sigma_{\text{iso}})] \quad (76)$$

We note that this average frequency corresponds to the sum of the isotropic shift and a scaled anisotropy, where the scaling factor is determined by the tilt angle. At the magic angle, i.e. when $\cos^2 \vartheta = \frac{1}{3}$ ($\vartheta = 54^\circ 44'$), only the isotropic term survives.

The chemical shift anisotropy is contained in σ_{zz} , where the z axis refers to the spinner axis. If we label the principal values of the chemical shift tensor (σ_{11} σ_{22} σ_{33}) and perform the transformation from the principal axis system to the spinner frame by the Euler angles (α β 0), we can express σ_{zz} by

$$\sigma_{zz} = \sigma_{11} \cos^2 \alpha \sin^2 \beta + \sigma_{22} \sin^2 \alpha \sin^2 \beta + \sigma_{33} \cos^2 \beta \quad (77)$$

In other words, a scaled anisotropic powder pattern is obtained where the shape and width depends on the angle θ . This procedure has led to the method of ‘variable angle spinning’ (VAS), which is discussed in a separate article (see **Variable Angle Sample Spinning**). A typical example for the type of sideband spectrum which is observed under magic angle spinning is shown in Figure 7.

If the full time dependence is considered, the FID can be expressed by the product of three phase factors,^{10,45,46}

$$g(t) = e^{i\varphi_0} e^{i\Phi_0(t)} e^{i\Phi_a(t)} \quad (78)$$

Figure 7 Phosphorus-31 powder spectra of solid dipalmitoyl-phosphatidylcholine under magic angle spinning conditions for different spinning frequencies ν_{Rot} including $\nu_{\text{Rot}} = 0$ (top). (Reproduced by permission of The American Physical Society from J. Herzfeld and A. Berger, *J. Chem. Phys.*, 1980, **73**, 6021. Courtesy of R. G. Griffin)

where

$$\varphi_0 = \frac{\omega_0}{\omega_R}(S_1 + 0.5S_2), \quad \Phi_0(t) = \bar{\omega}t \quad (78a)$$

$$\begin{aligned}\Phi_a(t) &= S_1 \sin \omega_R t + C_1 \cos \omega_R t + S_2 \sin 2\omega_R t \\ &\quad + C_2 \cos 2\omega_R t\end{aligned}\quad (78b)$$

with the parameters S_1 , S_2 , C_1 , and C_2 as defined in the previous section [see equation (76)].

The first term in equation (84) sets the initial phase, the second one represents the isotropic part of the shift tensor, and the third one the anisotropic part. All these parameters depend on the tilt angle ϑ of the spinner and the Euler angles (α β γ). In the case of a powder sample, the FID must be averaged over

the angles ($\alpha \beta \gamma$), which are conveniently expressed with respect to the principal axis system. The anisotropic part $\Phi_a(t) = \Phi_a(t - n2\pi/\omega_R)$ with $n = 0, 1, 2, \dots$ shows cyclic behavior, which leads to the creation of sidebands in the spectrum,^{45,46}

$$e^{i\Phi_a(t)} = \sum_{n=-\infty}^{\infty} F_n^* F_n e^{in\omega_R t} \quad (79)$$

where the sideband intensity $I_n = F_n^* F_n$ can be calculated from¹⁰

$$F_n = \sum_{k,l,m=-\infty}^{\infty} J_{n-k-2l-2m} \left(\frac{C_1}{\omega_R} \right) J_k \left(\frac{S_1}{\omega_R} \right) J_l \left(\frac{C_2}{2\omega_R} \right) \times J_m \left(\frac{S_2}{2\omega_R} \right) e^{-i\pi(k+m)/2} \quad (80)$$

Herzfeld and Berger⁴⁶ have calculated graphs from which the shift tensor elements can be determined from sideband intensities.

4.3 Rapid Molecular Rotation

The spectra corresponding to rapid molecular rotation follow directly from the treatment presented in Section 4.2. Instead of the spinner axis, a molecular rotation axis must be chosen. Because the rotation is considered to be rapid, i.e., $\omega_R \gg \Delta\omega$, where $\Delta\omega$ represents the frequency spread or anisotropy of the interaction, only the average frequency according to equation (82) contributes to the spectrum. In the case of a powder sample, the appropriate powder average must be calculated.

However, there is no free rotation in solids. Molecular reorientation always proceeds through jumps between potential wells that correspond to different orientations of the molecule. The corresponding line shift or splitting for a particular orientation of the molecule can be readily calculated by using the transformation properties of tensor interactions, as outlined in Section 4.1. Under rapid hopping conditions, an average tensor is observed that results from the average over all possible orientations. In the special case where a unique axis can be defined for the reorientation of the molecule and where the symmetry of this axis is at least threefold, this unique axis plays the role of a 'rotation axis', and the same equations as in Section 4.2 can be applied. As an example of 'rapid flipping', one can consider the limiting spectra in Figure 8.

The procedure for the general case of molecular reorientation is discussed in the following section.

4.4 Molecular Rotational Exchange

Molecular jumps between different orientations numbered j result in different eigenfrequencies ω_j . For simplicity, we discuss only single lines as observed in chemical shift spectra. However, the extension to line splitting as observed in quadrupolar or spin-spin coupling spectra is straightforward if only single quantum transitions are considered. In this case, the corresponding spectra can be treated as single lines. In fact, soon after the discovery of NMR, line narrowing due to molecular rotation in the solid state was observed by Andrew and Eades⁴⁷ in solid benzene. Since then, it was realized that characteristic changes in the NMR/ESR spectra occur under

Figure 8 Calculated powder spectra of an axially symmetric shift tensor under 180° jumps about an axis which is tilted by $54^\circ 44'$ (magic angle) with respect to the symmetry axis. The relative jump rate κ with respect to the total anisotropy ($\omega_{\parallel} - \omega_{\perp}$) is indicated. Note that in the fast motion limit ($\kappa = 100$) a nonaxially symmetric average tensor results. (Reproduced by permission of Springer-Verlag from M. Mehring, *Principles of High Resolution NMR in Solids*, Springer-Verlag, Berlin, 1983, p. 58)

molecular reorientation, and lineshape calculations became mandatory in order to extract the molecular dynamics from the spectra.^{48–53} Surprisingly, in inorganic solids, 'molecular' rotations were also observed in temperature-dependent NMR shift spectra.⁵⁴

As an example of a simple molecular two-site jump, we consider an axially symmetric shift or electric field gradient tensor. The corresponding powder spectrum for the shift tensor is shown in Figure 3 (top), while the spectrum for the electric field gradient tensor (spin $I = 1$) would resemble the Pake pattern shown in Figure 3 (bottom). Under rapid 180° molecular jumps about an axis tilted at the magic angle ($54^\circ 44'$) with respect to the unique axis of the tensor, a complete nonaxially symmetric ($\eta = 1$) tensor results. This could be observed for the shift tensor of ^1H in H_2O and for the electric field gradient tensor of ^2D in D_2O , for example. The variation of the lineshape for different jump rates κ between the extreme situations ($\kappa = 0$ and $\kappa = \infty$) is shown in Figure 8.

In order to calculate spectra like those displayed in Figure 8, we need to write down and solve the corresponding equation of motion. For every orientational site j , a site-specific FID $M_j(t)$ contributes to the total FID, with a probability p_j corresponding to the a priori probability that site j is occupied. Microscopic reversibility requires that $\kappa_{jk}p_k = \kappa_{kj}p_j$ where $\kappa_{jk} = \tau_{jk}^{-1}$ is the

Figure 9 (a) Calculated and (b) measured powder spectra for a random jumping tetrahedron with jump rates τ^{-1} . The measured spectra (b) obtained from ^{31}P in solid white phosphorus in the β phase compare very well with the calculated spectra (a). The values for the jump rates τ^{-1} of the experimental spectra were obtained from T_1 data. (Reproduced by permission of Elsevier Publishing Co. from H. W. Spiess, R. Grosescu, and U. Haeberlen, *Chem. Phys.*, 1974, **6**, 226)

jump rate from site k to site j . The equation of motion for $M_j(t)$ can now be written as

$$\frac{d}{dt} M_j(t) = i\omega_j M_j(t) - \frac{1}{T_{2j}} M_j(t) + \sum_k \kappa_{jk} M_k(t) \quad (81)$$

where additional transversal spin relaxation processes are collected in T_{2j} . By defining the column vector $\mathbf{M}(t)$ consisting of N elements $M_j(t)$ with $j = 1, 2, \dots, N$, equation (88) can be expressed in matrix form as

$$\frac{d}{dt} \mathbf{M}(t) = (i\mathbf{\Omega} + \mathbf{\Gamma}) \mathbf{M}(t) \quad (82)$$

where $\mathbf{\Omega}$ represents a diagonal matrix with diagonal elements ω_j and $\mathbf{\Gamma}$ corresponds to the jump matrix with elements $\kappa_{jk} = \tau_{jk}^{-1}$, where the diagonal elements are replaced by $\kappa_{jj} = 1/T_{2j}$. Since the total FID consists of the sum of $M_j(t)$ over all j , the solution of equation (89) can be formally expressed as

$$g(t) = \mathbf{1} \exp[(i\mathbf{\Omega} + \mathbf{\Gamma})t] \mathbf{p} \quad (83)$$

where $\mathbf{1} = (1, 1, \dots, 1)$ is an N -dimensional row 'one-vector' and $\mathbf{p} = (p_1, p_2, \dots, p_N)$ represents the a priori probability vector. The NMR spectrum is obtained after Fourier transformation of equation (90), which leads to the lineshape expression

$$I(\omega) = \text{Re}[\mathbf{1} \mathbf{A}(\omega)^{-1} \mathbf{p}] \quad (84)$$

where $\mathbf{A}(\omega) = i(\omega \mathbf{E} - \mathbf{\Omega}) + \mathbf{\Gamma}$ and $\mathbf{E}$ is the $N \times N$ unit matrix.

Although the matrix $\mathbf{A}(\omega)$ is a non-Hermitian complex matrix, there are numerical procedures to diagonalize it. Let us assume a transformation matrix $\mathbf{S}$ exists:

$$\mathbf{S}^{-1}(\mathbf{\Omega} + \mathbf{\Gamma})\mathbf{S} = \lambda \quad (85)$$

where $\lambda_{ij} = \lambda_j \delta_{ij}$, with eigenvalues λ_j . FID $g(t)$ and lineshape $I(\omega)$ can be expressed as a single sum over N elements as⁵⁵

$$g(t) = \sum_{j=1}^N (\mathbf{1S})_j e^{\lambda_j t} (\mathbf{S}^{-1}\mathbf{p})_j \quad (86a)$$

$$I(\omega) = \text{Re} \sum_{j=1}^N \frac{(\mathbf{1S})_j (\mathbf{S}^{-1}\mathbf{p})_j}{i\omega - \lambda_j} \quad (86b)$$

In the case of powder samples, the appropriate powder average has to be performed. An example of such a calculation is shown in Figure 9. Subtle details of the molecular motion, including the jump angles, can be determined from such an analysis. This type of molecular exchange spectroscopy turned out to be very useful in the investigation of molecular motions in polymers.⁵⁶

5 ORIGIN OF INTERNAL INTERACTIONS

There are articles in this Encyclopedia on the theoretical calculation of spin interactions. Therefore, I shall only outline some essential features of these interactions here.

5.1 Chemical Shift

Shielding of the nuclear spins in condensed matter was noticed and treated theoretically soon after the discovery of NMR.^{11,57,58} The local magnetic field $\mathbf{B}_{\text{local}}$ at the nuclear site deviates from the externally applied field $\mathbf{B}_0$ due to the induced magnetic field $\mathbf{B}_{\text{ind}}$

$$\mathbf{B}_{\text{local}} = (\mathbf{1} - \sigma) \mathbf{B}_0 = \mathbf{B}_0 - \mathbf{B}_{\text{ind}} \quad (87)$$

(with $\mathbf{1}$ the unit tensor), where

$$\mathbf{B}_{\text{ind}} = (\sigma_{\text{dia}} + \sigma_{\text{para}}) \mathbf{B}_0 \quad (88)$$

which can be viewed as being caused by induced orbital currents:

$$\mathbf{B}_{\text{ind}} = \frac{\mu_0}{4\pi} \int \frac{(\mathbf{r} - \mathbf{R}) \times \mathbf{j}(\mathbf{r})}{|\mathbf{r} - \mathbf{R}|^3} d^3r \quad (89)$$

It is convenient to separate the chemical shift tensor and the corresponding currents into 'diamagnetic' (σ_{d} , $\mathbf{j}_{\text{d}}$) or 'shielding' and 'paramagnetic' (σ_{p} , $\mathbf{j}_{\text{p}}$) or 'deshielding' contributions. The diamagnetic part is caused by diamagnetic orbital currents resulting from Lenz's rule (shielding), which leads to positive values (by definition) of σ_{d} , whereas the paramagnetic part is caused by paramagnetic orbital currents due to partial quenching of the orbital angular momentum (second-order effect), which leads to an enhanced local field and therefore negative values of σ_{p} . From the definition of these orbital currents,

$$\mathbf{j} = \mathbf{j}_{\text{d}} + \mathbf{j}_{\text{p}} \quad (90)$$

$$\mathbf{j}_d = -\frac{e}{mc} \mathbf{A} \psi^* \psi \quad (91)$$

with vector potential $\mathbf{A}$, and

$$\mathbf{j}_p = \frac{ie\hbar}{2m} [\psi^* \text{grad } \psi - \psi \text{grad } \psi^*] \quad (92)$$

it follows that knowledge of the electronic wave function in the presence of the static magnetic field is required in order to calculate the chemical shift tensor. Under the condition $\text{div } \mathbf{j} = 0$ and $\mathbf{A} = \frac{1}{2} \mathbf{B} \times (\mathbf{r} - \mathbf{R})$, the induced field vector can be calculated from the expression^{11,59-63}

$$\begin{aligned} \mathbf{B}_{\text{ind}} = & \left\{ -\frac{\mu_0}{4\pi} \frac{e^2}{2m} \langle 0 | \sum_j \frac{1}{r_j^3} (-x_j z_j \mathbf{I} - y_j z_j \mathbf{j} + (x_j^2 + y_j^2) \mathbf{k}) | 0 \rangle \right. \\ & + \frac{\mu_0}{4\pi} \frac{e^2 \hbar^2}{2m^2} \sum_n \frac{1}{E_n - E_0} \left[\langle 0 | \sum_j \frac{\hat{\mathbf{L}}_j}{r_j^3} | n \rangle \langle n | \sum_k \hat{\mathbf{L}}_{zk} | 0 \rangle \right. \\ & \left. \left. + \langle 0 | \sum_k \hat{\mathbf{L}}_{zk} | n \rangle \langle n | \sum_j \frac{\hat{\mathbf{L}}_j}{r_j^3} | 0 \rangle \right] \right\} B_0 \end{aligned} \quad (93)$$

where a summation over the electronic ground state $|0\rangle$ as well as excited states $|n\rangle$ is required. In deriving equation (100), it is assumed that the magnetic field is applied parallel to the z axis and only terms linear in B_0 are retained. $\hat{\mathbf{L}}_j$ is the angular momentum operator of electron j . Equation (100) was derived by Ramsey.¹¹ It consists of the (negative) diamagnetic part, which contains only a summation over electrons in the ground state, as well as the (positive) paramagnetic part, which involves summation over excited states.

The calculation of chemical shift tensors is by no means a trivial task. For reliable calculations on molecules and other delocalized electronic systems ‘gauge independent atomic orbitals’ (GIAO) must be applied in the LCAO–MO scheme. One of the very successful and more recent methods applies an ‘individual gauge for localized orbitals’ (IGLO). For a review of this technique consult Kutzelnigg et al.^{64,65} From their work, a plot of the diamagnetic, the paramagnetic, and the total orbital current in the benzene molecule is displayed in Figure 10. Note that a simple ring current picture, as is sometimes invoked, is not applicable.

5.2 Knight Shift

The Knight shift is caused by the hyperfine interaction of nuclear spins with electron spins as discussed in Section 2.1. The complete electron–nucleus interaction is summarized in the Hamiltonian

$$\begin{aligned} \hat{\mathcal{H}}_{\text{en}} = & \frac{\mu_0}{4\pi} \gamma_e \gamma_n \hbar^2 \sum_{i,j} \left[\frac{8}{3} \pi \hat{\mathbf{I}}_i \cdot \hat{\mathbf{S}}_j \delta(r_{ij}) \right. \\ & \left. + 3 \frac{(\hat{\mathbf{I}}_i \cdot \mathbf{r}_{ij})(\hat{\mathbf{S}}_j \cdot \mathbf{r}_{ij})}{r_{ij}^5} - \frac{\hat{\mathbf{I}}_i \cdot \hat{\mathbf{S}}_j}{r_{ij}^3} \right] \end{aligned} \quad (94)$$

where the electron spins $\mathbf{S}_j$ couple to the nuclear spins $\mathbf{I}_i$ via the Fermi contact term (first part) and the dipolar term (second and third parts). An NMR line shift results only if the electronic spin motion is much faster than the hyperfine interaction. This is the situation in metals, but also in some rapidly exchanging or diffusing electron spin systems.

Figure 10 (a) Diamagnetic, (b) paramagnetic, and (c) total orbital currents in benzene, derived by the IGLO method, in an external magnetic field $\mathbf{B}_0$ perpendicular to the benzene ring. Chemical shift tensors for protons and ^{13}C can be calculated according to the Biot–Savart law [equation (96)]. (Reproduced by permission of Kluwer from W. Kutzelnigg, C.v. Wüllen, U. Fleischer, R. Franke, and T.v. Mourik, in *Nuclear Magnetic Shielding and Molecular Structure*, ed. J. Tossell, Kluwer, Dordrecht, 1993, p. 141)

(Reproduced by permission of The American Physical Society from D. Köngeter and M. Mehring, *Phys. Rev. B*, 1989, **39**, 6361)

Although the corresponding NMR line shift was first reported in metals by W. Knight, it also applies to magnetic systems if the requirement of rapid spin diffusion is met. The classical Knight shift refers to the isotropic Knight shift, which is caused by the Fermi contact term,

$$K_{\text{iso}} = \frac{8}{3} \pi \langle |u_k(0)|^2 \rangle_{E_F} \frac{\chi_s}{4\pi n_e} \quad (95)$$

where the electronic wavefunction $\psi_k = u_k(\mathbf{r})e^{i\mathbf{k}\cdot\mathbf{r}}$ for wavevector $\mathbf{k}$ is a Bloch function consisting of a lattice periodic function $u_k(\mathbf{r})$ and a planewave function $e^{i\mathbf{k}\cdot\mathbf{r}}$. Since an average over the Fermi surface is performed, the Knight shift in its classical form is a measure of the s-wave character of the conduction electrons at the nuclear site and the conduction electron susceptibility χ_s . n_e is the number density of the conduction electrons, which must be replaced by Avogadro's number when the molar susceptibility is used. However, in general conductors, including organic conductors, a number of non-s orbitals contribute to the hyperfine interaction, and the Fermi contact term makes only a minor contribution to the Knight shift. For the isotropic Knight shift, 'core polarization' effects usually give larger contributions than the Fermi contact term. Often the dipolar part is significant, and leads to Knight shift anisotropy. Nevertheless, one can rigorously summarize all these contributions in the simple relation

$$K_{zz}^{(j)} = \hbar A_{zz}^{(j)} \left(\frac{\gamma_e}{\gamma_n} \right) \chi(q=0) \quad (96)$$

where, besides known parameters, the product of the z component of the local hyperfine tensor $A_{zz}^{(j)}$ (in rad s⁻¹) at nuclear site j and the reduced electron spin susceptibility $\chi(q=0)$ (in J⁻¹) results in the z component of the Knight shift tensor. Note that the full symmetric part of the Knight shift tensor is contained in the orientational dependence of K_{zz} . The reduced electron spin susceptibility $\chi(q=0)$ depends on the density of states at the Fermi level $D(E_F)$, and is in case of uncorrelated conduction electrons given by $\chi(q=0) = \frac{1}{4} D(E_F)$. It is related to the ordinary electron spin susceptibility χ_s by $\chi_s = \mu_0 n_e \gamma_e^2 \hbar^2 \chi(q=0)$, where n_e is the electron number density. Once the local hyperfine interaction is known, the Knight shift allows a determination of the electronic spin susceptibility,

even in the superconducting state, where the bulk susceptibility is dominated by diamagnetic shielding. Note that all quantities used here are given in SI units and χ_s is a dimensionless parameter.

Since the susceptibility is a global parameter, the site selective Knight shift reflects the hyperfine interaction and therefore the electron spin density at the particular nuclear site. This has been utilized in the determination of the site selective electron spin density, i.e. the amplitude of the conduction electron wave function, as in the organic conductor (fluoranthenyl)₂PF₆ displayed in Figure 11. For more details, the reader is referred to the specialized literature.^{4,5,66,67}

5.3 Electric Field Gradients

Quadrupolar interaction parameters such as ω_Q and η determined from NMR/NQR spectra directly lead to the electric field gradient at the nuclear site.⁶⁸ In order to calculate this electric field gradient, the charge distribution $\rho(\mathbf{r})$ must be known. The calculation of the electric field gradient V_{zz} is conveniently separated into an ionic contribution where summation takes place over all ions with charge q_j at position j and an electronic contribution where integration over the electronic charge density is considered.^{69–71}

$$V_{zz} = \frac{1}{4\pi\epsilon_0} \sum_j (1 - \gamma_\infty) q_j \left(\frac{3 \cos^2 \vartheta_j - 1}{r_j^3} \right) - \int [1 - \gamma(r)] \rho(r) \left(\frac{3 \cos^2 \vartheta - 1}{r^3} \right) d^3r \quad (97)$$

The parameters γ_∞ and $\gamma(r)$ are so-called Sternheimer factors which take the enhancement of the electric field gradient at the nuclear site due to 'core polarization' into account. The electronic charge density $\rho(\mathbf{r}) = e\psi^*\psi$ is derived from an MO-type calculation which must provide accurate wave functions ψ . Valuable information has been obtained from quadrupole

Figure 12 Difference electron density between the crystalline (calculated by the LAPW method) and the superposed ionic charge density in YBa₂Cu₃O₇, together with a drawing of the unit cell. The charge density contour plot corresponds to a plane parallel to the b and c axes through the Cu(1)–O(1) chains. Maxima and minima are labelled in units of $e \text{ \AA}^{-3}$. Dashed lines correspond to negative charge density, and solid lines to positive charge density. (Reproduced by permission of the American Physical Society from K. Schwarz, C. Ambrosch-Draxl, and P. Blaha, *Phys. Rev. B*, 1990, **42**, 2052. Courtesy of K. Schwarz)

interactions in different types of solids²⁵ and, in particular, in metals.^{66,67,72}

In recent years, ‘local density functional’-type calculations have provided accurate quadrupole coupling parameters in molecules as well as in solids. As an example, Figure 12 shows the charge density difference at different nuclear sites in the unit cell of the high temperature superconductor $\text{YBa}_2\text{Cu}_3\text{O}_7$, which was calculated within the ‘local density approximation’ (LDA) without any adjustable parameter and which resulted in quadrupolar coupling constants in agreement with experimentally determined values from NMR/NQR experiments.^{73,74}

5.4 Spherical Tensors

$$\hat{\mathcal{H}}_{\text{int}} = \hbar \sum_{l=0}^{l_{\text{max}}} \sum_{m=-l}^{+l} (-1)^m A^{(l,m)} \hat{T}^{(l,-m)} \quad (98)$$

$$\begin{aligned} \hat{\mathcal{H}}_{\text{int}} = \hbar \{ & A^{(0,0)} \hat{T}^{(0,0)} + A^{(1,0)} \hat{T}^{(1,0)} - (A^{(1,1)} \hat{T}^{(1,-1)} + A^{(1,-1)} \hat{T}^{(1,1)}) \\ & + A^{(2,0)} \hat{T}^{(2,0)} - (A^{(2,1)} \hat{T}^{(2,-1)} + A^{(2,-1)} \hat{T}^{(2,1)}) \\ & + A^{(2,2)} \hat{T}^{(2,-2)} + A^{(2,-2)} \hat{T}^{(2,2)} \} \end{aligned} \quad (99)$$

$$\hat{T}^{(l,m)} = R(\alpha\beta\gamma) \hat{T}^{(l,m)} R^{-1}(\alpha\beta\gamma) = \sum_{p=-l}^{+l} \hat{T}^{(l,p)} D_{pm}^l(\alpha\beta\gamma) \quad (100)$$

Since the electric field gradient tensor $\{V_{\alpha\beta}\}$ is traceless, only the $l = 2$ components of the spherical tensors are relevant in the case of the quadrupolar interaction. The following relations result:

$$\left. \begin{aligned} A^{(2,0)} &= 3\sqrt{\frac{1}{6}} K_Q V_{zz} \\ A^{(2,\pm 1)} &= \mp K_Q (V_{xz} \pm iV_{yz}) \\ A^{(2,\pm 2)} &= K_Q [\frac{1}{2}(V_{xx} - V_{yy}) \pm iV_{xy}] \\ T^{(2,0)} &= \frac{1}{\sqrt{6}} [3\hat{I}_z^2 - I(I+1)] \\ T^{(2,\pm 1)} &= \mp \frac{1}{2} (\hat{I}_z \hat{I}_{\pm} + \hat{I}_{\pm} \hat{I}_z) \\ T^{(2,\pm 2)} &= \frac{1}{2} \hat{I}_{\pm} \hat{I}_{\pm} \end{aligned} \right\} \quad (101)$$

Spin–spin interactions require in general all nine tensor elements. The relation between the spherical and Cartesian tensors is summarized in Tables 2–7.

Only in the special case of the dipole–dipole interaction does the isotropic part, as well as the antisymmetric part, vanish, and only the $l = 2$ terms survive.

5.5 Wigner Rotation Matrices

Some of the most frequently used Wigner rotation matrices $d_{mm'}^j(\beta)$ are listed in Table 8.

1 INTRODUCTION

Nuclear magnetic resonance is uniquely capable of revealing structure and dynamics on a molecular level. An understanding of nuclear spin relaxation is fundamental to an understanding of nuclear magnetic resonance in general. The theoretical framework needed to promote this understanding is conveniently constructed in terms of the time evolution of the density operator under the influence of some Hamiltonian as expressed by the Liouville–von Neuman equation. The emphasis here will be on molecules in liquids, though many of the principles presented are applicable to solids and gases. The experimental observables of NMR are oscillatory magnetizations induced in a sample as a consequence of subjecting it to various static and time-varying magnetic fields. The quantum mechanical operators corresponding to these observables act only on the nuclear spin degrees of freedom of the system. Furthermore, these operators are proportional to the spin angular momentum operators or products thereof, and, hence, can be dealt with using finite basis sets of states or operators. Relaxation, however, is a consequence of interactions between the nuclear spins and the rest of the system, referred to as the ‘lattice’. In most cases, the lattice cannot be treated exactly using quantum mechanics, because the density operator and the Hamiltonian cannot be defined exactly. The strategy generally employed, then, is to treat the effects of the lattice classically as a random time-dependent modulation of the nuclear spin operators while retaining a quantum mechanical description of the nuclear spins themselves. All externally applied magnetic fields are likewise treated classically. Our goal is to derive equations that correctly describe the observed temporal behavior of the experimental observables. This is done by proposing a Hamiltonian for the system under study, solving the Liouville–von Neuman equation for the time evolution of the density operator, computing the expected time evolution of the experimental observables, and comparing the result with measured values of these observables. Secondly, one wants to extract from this temporal behavior of the observables information about the fundamental nature of the system under investigation. For example, internuclear distances and rates of molecular reorientation due to Brownian motion can dramatically affect the

results of an NMR experiment. How can this kind of information be extracted from the behavior of the magnetization in a sample as a function of time? This article will lay out the theoretical framework of NMR experiments, with emphasis on an understanding of nuclear spin relaxation in liquids.

This article presumes a basic knowledge of the nuclear magnetic resonance phenomenon, including nuclear spin polarization in an external static magnetic field and interaction of nuclear spins with applied radiofrequency fields. For those not acquainted with these concepts, several basic texts may be consulted.^{1–3} The reader is assumed to have some grasp of basic quantum mechanics and angular momentum theory at the level generally taught in undergraduate physical chemistry courses. Some command of linear algebra and integral and differential calculus is also assumed. All abbreviations and symbols are either defined in the endpapers or are defined in context. Vectors and matrices will be distinguished by bold italic and bold roman type, respectively, and the same symbol in normal weight type will denote the magnitude of a vector or, with appropriate subscripts, components of a vector or elements of a matrix. Quantum mechanical operators will have a hat, for example, $\hat{H}$. Liouville space operators will have a double hat, for example $\hat{\hat{L}}$.

It is a familiar concept that the wavefunction embodies all that can be known about a quantum mechanical system and that any wavefunction can be expressed as a linear combination of the members of a complete set of eigenfunctions of the Hamiltonian of the system. However, in NMR, the density operator has proven to be a more convenient vehicle for this information, and the density operator, the Hamiltonian, and all other operators associated with the system can be cast as linear combinations of a complete set of orthonormal operators. These two descriptions are completely equivalent, and each can be formulated from the general concepts embodied in the bracket notation introduced by Dirac⁴ to describe abstract vector spaces. For nuclear spin systems in liquids, it is often possible to focus on a small number of spins (all the spins in one molecule, for example) and to consider the macroscopic sample as an ensemble of such systems, identical in their dependence on quantum mechanical operators but sampling the distribution of random classical variables. Since each nuclear spin has only a small number of eigenstates and the number of eigenstates for the whole system is the product of the numbers for each of the component spins, the necessary mathematics reduces, by means of an ensemble average, to a problem in linear algebra of reasonable dimension. In the following sections, the mathematics needed to discuss most of the experiments done on liquid samples will be formulated. Space limitations make it impossible to give a completely detailed exposition; for this, the reader may consult several excellent texts.^{5–9}

2 OPERATORS AND OPERATOR BASES

When a quantum mechanical system has a finite number of discrete energy levels (suppose there are n of them), the operators and states of the system can be represented as matrices and vectors in an n -dimensional vector space. Thus, the algebra of abstract n -dimensional vector spaces is essential to the theory we wish to develop. Dirac developed a convenient notation for describing these concepts.

2.1 Dirac Bracket Notation

For now, let us develop the bracket notation in a very abstract sense. It is important to realize that the bracket notation is just a formalism and can be applied to represent any desired vector space. Later, we shall apply it to both Hilbert and Liouville representations of the density operator. In the following equation is defined something called a *bra* and something called a *ket*:

$$\langle \text{bra} | (c) | \text{ket} \rangle \quad (1)$$

Bras and kets may have any kind of label inside to distinguish one from another. A ket may be converted into the corresponding bra by taking the Hermitian conjugate or adjoint, i.e., the complex conjugate transpose, and, of course, a bra can be converted into a ket in the same manner:

$$\langle \text{bra} | = [(| \text{ket} \rangle)^*]^T = (| \text{ket} \rangle)^\dagger \quad (2)$$

Multiplication of a bra and a ket in that order yields a number that can be real, imaginary, or complex:

$$\langle \text{bra} | \text{ket} \rangle = c \quad (3)$$

Note that this *scalar product* is not commutative, as we shall see in equation (9). Equation (3) is a key concept. In what follows, one must be able to recognize the $\langle | \rangle$ construct as a number that commutes with operators, bras, and kets. The scalar product is linear:

$$\left. \begin{aligned} \langle \text{bra} | (| \text{ket}_1 \rangle + | \text{ket}_2 \rangle) \rangle &= \langle \text{bra} | \text{ket}_1 \rangle + \langle \text{bra} | \text{ket}_2 \rangle \\ (\langle \text{bra}_1 | + \langle \text{bra}_2 |) | \text{ket} \rangle &= \langle \text{bra}_1 | \text{ket} \rangle + \langle \text{bra}_2 | \text{ket} \rangle \end{aligned} \right\} \quad (4)$$

Next we define something called an *operator* that converts a ket into some other ket:

$$\widehat{Op} | \text{ket} \rangle = | \text{new ket} \rangle \quad (5)$$

Operators will be distinguished by a hat (circumflex). Operators do not, in general, commute. The identity operator $\hat{E}$ just leaves a ket unaltered:

$$\hat{E} | \text{ket} \rangle = | \text{ket} \rangle \quad (6)$$

The identity operator does commute with all other operators.

Taking the adjoint of both sides of equation (5) yields the following relationship, which shows how an operator can act to the left on a bra:

$$(\widehat{Op} | \text{ket} \rangle)^\dagger = \langle \text{bra} | \widehat{Op}^\dagger = \langle \text{new bra} | \quad (7)$$

If $\widehat{Op}^\dagger = \widehat{Op}$, the operator is said to be *Hermitian* or *self-adjoint*.

If an operator acting on a ket yields the same ket multiplied by a number c (perhaps complex), the ket is said to be an *eigenket* of the operator, and c is the *eigenvalue*:

$$\widehat{Op} | \text{ket} \rangle = c | \text{ket} \rangle \quad (8)$$

As mentioned above, multiplication of bras and kets is not commutative, so the question arises of the meaning of the following product of a ket with a bra:

$$| \text{ket} \rangle \langle \text{bra} | = \text{operator} \quad (9)$$

This is called the *outer product* or *tensor product* of the bra and ket. Equation (9) asserts that this combination is an operator. This assertion can be easily proven by operating on some ket:

$$| a \rangle \langle b | c \rangle = | a \rangle \langle b | c \rangle = | a \rangle n_{bc} = n_{bc} | a \rangle \quad (10)$$

Remember that $\langle b | c \rangle$ is just a number, by equation (3), and a number will commute with a ket. Thus, $| a \rangle \langle b |$ satisfies the definition of an operator as in equation (5), because it produces a new ket $| a \rangle$ from $| c \rangle$. The numerical coefficient involved is not a problem, because a number times a ket is still a ket. The fact that one can reinterpret or regroup bras and kets in this way is a key concept of the formalism. In Section 2.2 it will become more obvious why these alternative interpretations are possible. We shall not put a hat over these operators, since there is no possibility of confusion; expressions of the type $| \rangle \langle |$ will always be interpretable as operators.

If we have a set of kets $\{ | i \rangle, i = 1, 2, 3, \dots, n \}$ such that

$$\langle i | j \rangle = \delta_{ij} \quad \text{for all } i, j = 1, 2, 3, \dots, n \quad (11)$$

then the set is said to be an *orthonormal* (orthogonal and normalized) basis. The Kronecker delta function is defined by

$$\delta_{ij} = \begin{cases} 1 & (i = j) \\ 0 & (i \neq j) \end{cases} \quad (12)$$

If for some member of the set $\langle i | i \rangle \neq 1$ then we simply define a new ket $| i' \rangle = | i \rangle / \langle i | i \rangle^{1/2}$ to replace $| i \rangle$ until all members of the set are normalized.

With just these simple rules for manipulating operators, bras, and kets as postulates, one can develop the mathematics necessary to treat nuclear spin dynamics.

2.2 Representations

Suppose we have some system in a state that corresponds to an abstract vector or ket designated as $| \psi(t) \rangle$. The indicated time dependence shows that the system may be evolving in time. We attempt to expand this state in the stationary orthonormal set of equation (11) as follows, and we want to know the form of the coefficients $c_i(t)$:

$$| \psi(t) \rangle = \sum_{i=1}^n c_i(t) | i \rangle \quad (13)$$

Multiplying from the left by $\langle i |$, a bra corresponding to one of the members of the basis set, and using equation (11) yields

$$\begin{aligned} \langle i | \psi(t) \rangle &= \langle i | \sum_{j=1}^n c_j(t) | j \rangle \\ &= \sum_{j=1}^n c_j(t) \langle i | j \rangle \\ &= \sum_{j=1}^n c_j(t) \delta_{ij} = c_i(t) \end{aligned} \quad (14)$$

The last step follows because, by equation (12), only the i th term survives in the sum. This is a formal prescription for computing the expansion coefficients; later, we shall see how it is implemented in real cases. The question of whether the set $\{|i\rangle\}$ is complete, i.e., contains all the basis vectors necessary to represent $|\psi(t)\rangle$, will not be addressed here. It will simply be asserted that such a set can be found. Taking the adjoint of both sides of equation (14) yields the analogous equation for bras:

$$\langle\psi(t)|i\rangle = c_i^*(t) \quad (15)$$

Having chosen a basis set, we can compute all the coefficients needed for equation (14) or equation (15). If these coefficients are arranged in a column or a row vector then we have the Hilbert space representation of the state (bra or ket) in the basis:

$$|\psi\rangle \xrightarrow{|i\rangle} \begin{bmatrix} \langle 1|\psi\rangle \\ \langle 2|\psi\rangle \\ \langle 3|\psi\rangle \\ \vdots \\ \langle n|\psi\rangle \end{bmatrix} = \begin{bmatrix} c_1 \\ c_2 \\ c_3 \\ \vdots \\ c_n \end{bmatrix} \quad (16a)$$

$$\begin{aligned} \langle\psi| \xrightarrow{|i\rangle} & [\langle\psi|1\rangle \quad \langle\psi|2\rangle \quad \langle\psi|3\rangle \quad \dots \quad \langle\psi|n\rangle] \\ & = [c_1^* \quad c_2^* \quad c_3^* \quad \dots \quad c_n^*] \end{aligned} \quad (16b)$$

A mapping of this sort is sometimes written with an equals sign in the literature. This is not consistent with the notation we have developed, because the state $|\psi\rangle$ is an abstraction implying no particular basis, whereas the vector representing $|\psi\rangle$ requires that a particular basis be chosen. It is also inconsistent to equate a wavefunction to a ket, because a wavefunction is a representation of the ket in a continuous rather than a discrete basis. The result is a function rather than a vector with discrete elements; that is why it is called a *wavefunction*. In this article, mappings of this sort will be indicated by an arrow as in equation (16). The basis used will be indicated as shown or will be obvious from the context.

Of course, the members of the basis set can themselves be represented in the basis. If the j th member of the basis is represented then all the elements of the vector will be zero except the j th, which is one:

$$|j\rangle \xrightarrow{|i\rangle} \begin{bmatrix} \langle 1|j\rangle \\ \langle 2|j\rangle \\ \vdots \\ \langle j|j\rangle \\ \vdots \\ \langle n|j\rangle \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 1 \\ \vdots \\ 0 \end{bmatrix} \quad (17a)$$

$$\begin{aligned} \langle j| \xrightarrow{|i\rangle} & [\langle j|1\rangle \quad \langle j|2\rangle \quad \dots \quad \langle j|j\rangle \quad \dots \quad \langle j|n\rangle] \\ & = [0 \quad 0 \quad \dots \quad 1 \quad \dots \quad 0] \end{aligned} \quad (17b)$$

If we rewrite equation (13) using the result in equation (14) and commute the number with the ket on the right, we have

$$\begin{aligned} |\psi(t)\rangle &= \sum_{i=1}^n \langle i|\psi(t)\rangle |i\rangle \\ &= \sum_{i=1}^n |i\rangle \langle i|\psi(t)\rangle \\ &= \left(\sum_{i=1}^n |i\rangle \langle i| \right) |\psi(t)\rangle \end{aligned} \quad (18)$$

Written this way, the implication is

$$\sum_{i=1}^n |i\rangle \langle i| = \hat{E} \quad (19)$$

Rearranging and reinterpreting the brackets in this way may seem quite strange at first, but the examples given below should clarify the formalism. The operators $|i\rangle \langle i|$ are called *projection operators* because they project from any state the part that projects on the i th basis state. Summing over all the projection operators then just gives the unit operator.

Suppose we have two alternative sets of basis states, $\{|a,i\rangle\}$ and $\{|b,i\rangle\}$, spanning the same vector space; then we can effect a transformation between the bases using projection operators as in equation (19). Projecting the b basis onto the a basis, we have

$$\begin{aligned} |b,i\rangle &= \left(\sum_{j=1}^n |a,j\rangle \langle a,j| \right) |b,i\rangle \\ &= \sum_{j=1}^n |a,j\rangle \langle a,j|b,i\rangle \\ &= \sum_{j=1}^n \langle a,j|b,i\rangle |a,j\rangle \end{aligned} \quad (20)$$

If we have an arbitrary state represented in the b basis, it can be transformed to the a basis as follows:

$$\begin{aligned} \psi &= \sum_{i=1}^n \langle b,i|\psi\rangle |b,i\rangle \\ &= \sum_{i=1}^n \langle b,i|\psi\rangle \sum_{j=1}^n \langle a,j|b,i\rangle |a,j\rangle \\ &= \sum_{i,j=1}^n \langle a,j|b,i\rangle \langle b,i|\psi\rangle |a,j\rangle \end{aligned} \quad (21a)$$

$$\begin{aligned} \langle\psi| &= \sum_{i=1}^n \langle\psi|b,i\rangle \langle b,i| \\ &= \sum_{i=1}^n \langle\psi|b,i\rangle \sum_{j=1}^n \langle b,i|a,j\rangle \langle a,j| \\ &= \sum_{i,j=1}^n \langle\psi|b,i\rangle \langle b,i|a,j\rangle \langle a,j| \end{aligned} \quad (21b)$$

4 LIOUVILLE EQUATION OF MOTION

Comparing these results with equations (16a) and (16b), it is apparent that equations (21a) and (21b) can be represented as follows:

$$\begin{aligned} & \begin{bmatrix} \langle a, 1|\psi \rangle \\ \langle a, 2|\psi \rangle \\ \langle a, 3|\psi \rangle \\ \vdots \\ \langle a, n|\psi \rangle \end{bmatrix} \\ &= \begin{bmatrix} \langle a, 1|b, 1 \rangle & \langle a, 1|b, 2 \rangle & \langle a, 1|b, 3 \rangle & \dots & \langle a, 1|b, n \rangle \\ \langle a, 2|b, 1 \rangle & \langle a, 2|b, 2 \rangle & \langle a, 2|b, 3 \rangle & \dots & \langle a, 2|b, n \rangle \\ \langle a, 3|b, 1 \rangle & \langle a, 3|b, 2 \rangle & \langle a, 3|b, 3 \rangle & \dots & \langle a, 3|b, n \rangle \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \langle a, n|b, 1 \rangle & \langle a, n|b, 2 \rangle & \langle a, n|b, 3 \rangle & \dots & \langle a, n|b, n \rangle \end{bmatrix} \\ &\quad \times \begin{bmatrix} \langle b, 1|\psi \rangle \\ \langle b, 2|\psi \rangle \\ \langle b, 3|\psi \rangle \\ \vdots \\ \langle b, n|\psi \rangle \end{bmatrix} \end{aligned} \quad (22a)$$

$$\begin{aligned} & [\langle \psi|a, 1 \rangle \quad \langle \psi|a, 2 \rangle \quad \langle \psi|a, 3 \rangle \quad \dots \quad \langle \psi|a, n \rangle] \\ &= [\langle \psi|b, 1 \rangle \quad \langle \psi|b, 2 \rangle \quad \langle \psi|b, 3 \rangle \quad \dots \quad \langle \psi|b, n \rangle] \\ &\quad \times \begin{bmatrix} \langle b, 1|a, 1 \rangle & \langle b, 1|a, 2 \rangle & \langle b, 1|a, 3 \rangle & \dots & \langle b, 1|a, n \rangle \\ \langle b, 2|a, 1 \rangle & \langle b, 2|a, 2 \rangle & \langle b, 2|a, 3 \rangle & \dots & \langle b, 2|a, n \rangle \\ \langle b, 3|a, 1 \rangle & \langle b, 3|a, 2 \rangle & \langle b, 3|a, 3 \rangle & \dots & \langle b, 3|a, n \rangle \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \langle b, n|a, 1 \rangle & \langle b, n|a, 2 \rangle & \langle b, n|a, 3 \rangle & \dots & \langle b, n|a, n \rangle \end{bmatrix} \end{aligned} \quad (22b)$$

Note that the columns of the first transformation matrix are merely the representation of the b basis kets in the a basis, while the rows are the representation of the a bras in the b basis. The second transformation matrix is the adjoint (complex conjugate transpose) of the first. If the two matrices are multiplied in either order, the result is a unit matrix, because the basis states are normalized. But this is just the definition of a unitary matrix. In compact matrix notation, we have

$$\psi_a = \mathbf{T}\psi_b, \quad \psi_a^\dagger = \psi_b^\dagger \mathbf{T}^\dagger \quad (23)$$

The unitary nature of the transformation is expressed as

$$\mathbf{T}\mathbf{T}^\dagger = \mathbf{T}^\dagger \mathbf{T} = \mathbf{E} = \mathbf{T}\mathbf{T}^{-1} = \mathbf{T}^{-1}\mathbf{T} \quad (24)$$

From these two equations, it is evident that the normalization of the state is preserved, regardless of the representation used:

$$\psi_a^\dagger \psi_a = \psi_b^\dagger \mathbf{T}^\dagger \mathbf{T} \psi_b = \psi_b^\dagger \psi_b \quad (25)$$

The inverse transformation can easily be derived. If $\psi_a = \mathbf{T}\psi_b$ then we have

$$\mathbf{T}^{-1}\mathbf{T}\psi_b = \mathbf{T}^{-1}\psi_a, \quad \psi_b = \mathbf{T}^{-1}\psi_a \quad (26)$$

But the inverse transformation is

$$\begin{aligned} |\psi\rangle &= \sum_{i=1}^n \langle a, i|\psi\rangle |a, i\rangle \\ &= \sum_{i=1}^n \langle a, i|\psi\rangle \sum_{j=1}^n \langle b, j|a, i\rangle |b, j\rangle \\ &= \sum_{i,j=1}^n \langle b, j|a, i\rangle \langle a, i|\psi\rangle |b, j\rangle \end{aligned} \quad (27)$$

Comparing equations (21a) and (27), the relationship between the a to b and b to a transforms is found to be

$$T_{ji}^* = \langle b, i|a, j\rangle^* = \langle a, j|b, i\rangle = T_{ij}^\dagger \quad (28)$$

which shows that the inverse transformation matrix $\mathbf{T}^{-1}$ is just the adjoint of the original matrix—but this is again just the definition of a unitary matrix. Examining equations (22a) and (22b), it is clear that the complex conjugate transpose of the transformation matrix is, indeed, the desired inverse transformation. This may be shown more easily by noting from equation (24) that $\mathbf{T}^\dagger = \mathbf{T}^{-1}$. Then, from equation (23), we have

$$\left. \begin{aligned} \mathbf{T}^\dagger \psi_a &= \mathbf{T}^\dagger \mathbf{T} \psi_b = \psi_b \\ \psi_a^\dagger \mathbf{T} &= \psi_b^\dagger \mathbf{T}^\dagger \mathbf{T} = \psi_b^\dagger \end{aligned} \right\} \quad (29)$$

We now turn to some relationships involving operators. Suppose one has some arbitrary operator $\hat{O}$. Using equation (19), we can write

$$\begin{aligned} \hat{O} &= \left(\sum_{i=1}^n |i\rangle \langle i| \right) \hat{O} \left(\sum_{j=1}^n |j\rangle \langle j| \right) \\ &= \sum_{i,j=1}^n |i\rangle \langle i| \hat{O} |j\rangle \langle j| \\ &= \sum_{i,j=1}^n \langle i| \hat{O} |j\rangle |i\rangle \langle j| \\ &= \sum_{i,j=1}^n c_{ij} |i\rangle \langle j| \end{aligned} \quad (30)$$

A unit operator can be inserted anywhere without affecting the equality. This equation is a prescription for writing any operator as a sum of operators $|i\rangle \langle j|$. Clearly, if there are n basis states $|i\rangle$ then there are n^2 basis operators $|i\rangle \langle j|$. If we multiply this equation from the left and right by a basis state, the result is a prescription for the coefficients c_{ij} :

$$\begin{aligned} \langle k| \hat{O} |l\rangle &= \langle k| \left(\sum_{i,j=1}^n c_{ij} |i\rangle \langle j| \right) |l\rangle \\ &= \sum_{i,j=1}^n c_{ij} \langle k|i\rangle \langle j|l\rangle \\ &= \sum_{i,j=1}^n c_{ij} \delta_{ki} \delta_{jl} = c_{kl} \end{aligned} \quad (31)$$

These coefficients are commonly called the *matrix elements* of the operator, and can be arranged in a matrix to form a Hilbert space representation of the operator:

$$\hat{O} \xrightarrow{|i\rangle} \mathbf{O} = \begin{bmatrix} \langle 1|\hat{O}|1\rangle & \langle 1|\hat{O}|2\rangle & \langle 1|\hat{O}|3\rangle & \dots & \langle 1|\hat{O}|n\rangle \\ \langle 2|\hat{O}|1\rangle & \langle 2|\hat{O}|2\rangle & \langle 2|\hat{O}|3\rangle & \dots & \langle 2|\hat{O}|n\rangle \\ \langle 3|\hat{O}|1\rangle & \langle 3|\hat{O}|2\rangle & \langle 3|\hat{O}|3\rangle & \dots & \langle 3|\hat{O}|n\rangle \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \langle n|\hat{O}|1\rangle & \langle n|\hat{O}|2\rangle & \langle n|\hat{O}|3\rangle & \dots & \langle n|\hat{O}|n\rangle \end{bmatrix} \quad (32)$$

Proceeding as in equation (25), we can write

$$\psi_a^\dagger \mathbf{O}_a \psi_a = \psi_b^\dagger \mathbf{T}^\dagger \mathbf{T} \mathbf{O}_a \mathbf{T}^\dagger \psi_b = \psi_b^\dagger \mathbf{O}_b \psi_b \quad (33)$$

where we have defined the operator in the b basis as

$$\mathbf{O}_b = \mathbf{T} \mathbf{O}_a \mathbf{T}^\dagger \quad (34)$$

Analogously, the basis operators themselves can be represented as follows to yield a matrix of all zero elements except the ij th:

$$\begin{aligned} |i\rangle\langle j| \xrightarrow{|i\rangle} & \begin{bmatrix} \langle 1|i\rangle\langle j|1\rangle & \langle 1|i\rangle\langle j|2\rangle & \dots & \langle 1|i\rangle\langle j|j\rangle & \dots & \langle 1|i\rangle\langle j|n\rangle \\ \langle 2|i\rangle\langle j|1\rangle & \langle 2|i\rangle\langle j|2\rangle & \dots & \langle 2|i\rangle\langle j|j\rangle & \dots & \langle 2|i\rangle\langle j|n\rangle \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ \langle i|i\rangle\langle j|1\rangle & \langle i|i\rangle\langle j|2\rangle & \dots & \langle i|i\rangle\langle j|j\rangle & \dots & \langle i|i\rangle\langle j|n\rangle \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ \langle n|i\rangle\langle j|1\rangle & \langle n|i\rangle\langle j|2\rangle & \dots & \langle n|i\rangle\langle j|j\rangle & \dots & \langle n|i\rangle\langle j|n\rangle \end{bmatrix} \\ &= \begin{bmatrix} 0 & 0 & \dots & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 1 & \dots & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 0 & \dots & 0 \end{bmatrix} \end{aligned} \quad (35)$$

This result can also be obtained from equations (17a) and (17b) by writing

$$\begin{aligned} & \begin{bmatrix} \langle 1|i\rangle \\ \langle 2|i\rangle \\ \vdots \\ \langle j|i\rangle \\ \vdots \\ \langle n|i\rangle \end{bmatrix} [\langle j|1\rangle \quad \langle j|2\rangle \quad \dots \quad \langle j|j\rangle \quad \dots \quad \langle j|n\rangle] \\ &= \begin{bmatrix} \langle 1|i\rangle\langle j|1\rangle & \langle 1|i\rangle\langle j|2\rangle & \dots & \langle 1|i\rangle\langle j|j\rangle & \dots & \langle 1|i\rangle\langle j|n\rangle \\ \langle 2|i\rangle\langle j|1\rangle & \langle 2|i\rangle\langle j|2\rangle & \dots & \langle 2|i\rangle\langle j|j\rangle & \dots & \langle 2|i\rangle\langle j|n\rangle \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ \langle i|i\rangle\langle j|1\rangle & \langle i|i\rangle\langle j|2\rangle & \dots & \langle i|i\rangle\langle j|j\rangle & \dots & \langle i|i\rangle\langle j|n\rangle \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ \langle n|i\rangle\langle j|1\rangle & \langle n|i\rangle\langle j|2\rangle & \dots & \langle n|i\rangle\langle j|j\rangle & \dots & \langle n|i\rangle\langle j|n\rangle \end{bmatrix} \end{aligned} \quad (36)$$

The basis operators are orthogonal, just as the basis states are; however, the inner product exemplified by equation (11) must

be replaced by the trace operation:

$$\begin{aligned} \text{Tr}(|j\rangle\langle k|l\rangle\langle m|) &= \sum_{i=1}^n \langle i|j\rangle\langle k|l\rangle\langle m|i\rangle \\ &= \langle k|l\rangle\langle m|j\rangle \\ &= \delta_{kl}\delta_{mj} \end{aligned} \quad (37)$$

In equation (37), the right-hand side will be nonzero if and only if $j = m$ and $k = l$; then

$$|j\rangle\langle k|k\rangle\langle j| = |j\rangle\langle k|(|j\rangle\langle k|)^\dagger \quad (38)$$

In order to simplify notation, we now make a mapping of the indices j and k of $|j\rangle\langle k|$ onto a single index i of $\hat{U}_i$. This is simply a relabeling of the basis operators. The exact nature of the mapping is arbitrary, except that there must be a one-to-one correspondence between the pair of indices j, k and the index i . The expression corresponding to equation (37) is then

$$\text{Tr}(\hat{U}_i \hat{U}_j^\dagger) = \delta_{ij} \quad (39)$$

This equation is the normalization condition for basis operators analogous to equation (11). Note that if the basis states used in equation (37) are normalized then these basis operators will also be normalized.

If we expand the generic operator $\hat{O}$ in terms of this basis set, the result is

$$\hat{O} = \sum_{i=1}^{n^2} c_i \hat{U}_i \quad (40)$$

Now, if this equation is multiplied by $\hat{U}_j^\dagger$ and the trace taken, a prescription is obtained for the expansion coefficients c_i :

$$\begin{aligned} \text{Tr}(\hat{O} \hat{U}_j^\dagger) &= \text{Tr}\left(\sum_{i=1}^{n^2} c_i \hat{U}_i \hat{U}_j^\dagger\right) \\ &= \sum_{i=1}^{n^2} c_i \text{Tr}(\hat{U}_i \hat{U}_j^\dagger) = \sum_{i=1}^{n^2} c_i \delta_{ij} = c_j \end{aligned} \quad (41)$$

Equation (40) may then be rewritten as

$$\hat{O} = \sum_{i=1}^{n^2} \text{Tr}(\hat{O} \hat{U}_i^\dagger) \hat{U}_i \quad (42)$$

The coefficients in this equation can be arranged in a vector to form the Liouville space representation of the operator:

$$\hat{O} \xrightarrow{\hat{U}_i} \begin{bmatrix} \text{Tr}(\hat{O} \hat{U}_1^\dagger) \\ \text{Tr}(\hat{O} \hat{U}_2^\dagger) \\ \text{Tr}(\hat{O} \hat{U}_3^\dagger) \\ \vdots \\ \text{Tr}(\hat{O} \hat{U}_{n^2}^\dagger) \end{bmatrix} \quad (43)$$

Note that this space is n^2 -dimensional.

As was done with basis states, it is possible to transform among alternative sets of basis operators. Consider a new operator basis $\{\hat{V}_i, i = 1, 2, 3, \dots, n^2\}$. These operators can be expressed in the original basis as

$$\hat{V}_i = \sum_{j=1}^{n^2} \text{Tr}(\hat{V}_i \hat{U}_j^\dagger) \hat{U}_j \quad (44)$$

Equation (42) can be written in terms of the $\hat{V}_i$; then equation (44) can be substituted:

$$\begin{aligned} \hat{O} &= \sum_{j=1}^{n^2} \text{Tr}(\hat{O} \hat{V}_j^\dagger) \hat{V}_j \\ &= \sum_{j=1}^{n^2} \text{Tr}(\hat{O} \hat{V}_j^\dagger) \sum_{i=1}^{n^2} \text{Tr}(\hat{V}_j \hat{U}_i^\dagger) \hat{U}_i \\ &= \sum_{i,j=1}^{n^2} \text{Tr}(\hat{V}_j \hat{U}_i^\dagger) \text{Tr}(\hat{O} \hat{V}_j^\dagger) \hat{U}_i \end{aligned} \quad (45)$$

Comparing equations (42) and (45), it is evident that the conversion of operator bases is accomplished as follows:

$$\text{Tr}(\hat{O} \hat{U}_i^\dagger) = \sum_{j=1}^{n^2} \text{Tr}(\hat{V}_j \hat{U}_i^\dagger) \text{Tr}(\hat{O} \hat{V}_j^\dagger) \quad (46)$$

In terms of the Liouville space representation, this can be written as

$$\begin{aligned} &\begin{bmatrix} \text{Tr}(\hat{O} \hat{U}_1^\dagger) \\ \text{Tr}(\hat{O} \hat{U}_2^\dagger) \\ \text{Tr}(\hat{O} \hat{U}_3^\dagger) \\ \vdots \\ \text{Tr}(\hat{O} \hat{U}_{n^2}^\dagger) \end{bmatrix} \\ &= \begin{bmatrix} \text{Tr}(\hat{V}_1 \hat{U}_1^\dagger) & \text{Tr}(\hat{V}_2 \hat{U}_1^\dagger) & \text{Tr}(\hat{V}_3 \hat{U}_1^\dagger) & \dots & \text{Tr}(\hat{V}_{n^2} \hat{U}_1^\dagger) \\ \text{Tr}(\hat{V}_1 \hat{U}_2^\dagger) & \text{Tr}(\hat{V}_2 \hat{U}_2^\dagger) & \text{Tr}(\hat{V}_3 \hat{U}_2^\dagger) & \dots & \text{Tr}(\hat{V}_{n^2} \hat{U}_2^\dagger) \\ \text{Tr}(\hat{V}_1 \hat{U}_3^\dagger) & \text{Tr}(\hat{V}_2 \hat{U}_3^\dagger) & \text{Tr}(\hat{V}_3 \hat{U}_3^\dagger) & \dots & \text{Tr}(\hat{V}_{n^2} \hat{U}_3^\dagger) \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \text{Tr}(\hat{V}_1 \hat{U}_{n^2}^\dagger) & \text{Tr}(\hat{V}_2 \hat{U}_{n^2}^\dagger) & \text{Tr}(\hat{V}_3 \hat{U}_{n^2}^\dagger) & \dots & \text{Tr}(\hat{V}_{n^2} \hat{U}_{n^2}^\dagger) \end{bmatrix} \\ &\quad \times \begin{bmatrix} \text{Tr}(\hat{O} \hat{V}_1^\dagger) \\ \text{Tr}(\hat{O} \hat{V}_2^\dagger) \\ \text{Tr}(\hat{O} \hat{V}_3^\dagger) \\ \vdots \\ \text{Tr}(\hat{O} \hat{V}_{n^2}^\dagger) \end{bmatrix} \end{aligned} \quad (47)$$

2.3 Direct Product Bases

It is quite common that one is able to derive a basis for two or more parts of a system using the techniques described in the previous section, but it is then desired to represent the whole

system so that interactions among the parts can be considered. For example, a molecule might contain two spins, say a ^{13}C nucleus and a ^1H nucleus. For this purpose, we introduce the *direct* or *outer product* of the subspaces to form the space appropriate for the whole system. One can form the direct products in either Hilbert space or Liouville space. The only new definitions needed are as follows. For vectors (states),

$$|\psi_1\rangle|\psi_2\rangle = |\psi\rangle \quad (48a)$$

$$\begin{bmatrix} \langle 1, 1|\psi_1\rangle \\ \langle 1, 2|\psi_1\rangle \\ \langle 1, 3|\psi_1\rangle \\ \vdots \\ \langle 1, n|\psi_1\rangle \end{bmatrix} \otimes \begin{bmatrix} \langle 2, 1|\psi_2\rangle \\ \langle 2, 2|\psi_2\rangle \\ \langle 2, 3|\psi_2\rangle \\ \vdots \\ \langle 2, m|\psi_2\rangle \end{bmatrix} = \begin{bmatrix} \langle 1, 1|\psi_1\rangle \begin{bmatrix} \langle 2, 1|\psi_2\rangle \\ \langle 2, 2|\psi_2\rangle \\ \langle 2, 3|\psi_2\rangle \\ \vdots \\ \langle 2, m|\psi_2\rangle \end{bmatrix} \\ \langle 1, 2|\psi_1\rangle \begin{bmatrix} \langle 2, 1|\psi_2\rangle \\ \langle 2, 2|\psi_2\rangle \\ \langle 2, 3|\psi_2\rangle \\ \vdots \\ \langle 2, m|\psi_2\rangle \end{bmatrix} \\ \langle 1, 3|\psi_1\rangle \begin{bmatrix} \langle 2, 1|\psi_2\rangle \\ \langle 2, 2|\psi_2\rangle \\ \langle 2, 3|\psi_2\rangle \\ \vdots \\ \langle 2, m|\psi_2\rangle \end{bmatrix} \\ \vdots \\ \langle 1, n|\psi_1\rangle \begin{bmatrix} \langle 2, 1|\psi_2\rangle \\ \langle 2, 2|\psi_2\rangle \\ \langle 2, 3|\psi_2\rangle \\ \vdots \\ \langle 2, m|\psi_2\rangle \end{bmatrix} \end{bmatrix} \quad (48b)$$

A slightly more condensed notation is required to make the corresponding definition for matrices (operators) manageable:

$$\hat{O} = \hat{O}^{(1)} \otimes \hat{O}^{(2)} \quad (49a)$$

$$\mathbf{O} = \begin{bmatrix} O_{1,1}^{(1)} \mathbf{O}^{(2)} & O_{1,2}^{(1)} \mathbf{O}^{(2)} & O_{1,3}^{(1)} \mathbf{O}^{(2)} & \dots & O_{1,n}^{(1)} \mathbf{O}^{(2)} \\ O_{2,1}^{(1)} \mathbf{O}^{(2)} & O_{2,2}^{(1)} \mathbf{O}^{(2)} & O_{2,3}^{(1)} \mathbf{O}^{(2)} & \dots & O_{2,n}^{(1)} \mathbf{O}^{(2)} \\ O_{3,1}^{(1)} \mathbf{O}^{(2)} & O_{3,2}^{(1)} \mathbf{O}^{(2)} & O_{3,3}^{(1)} \mathbf{O}^{(2)} & \dots & O_{3,n}^{(1)} \mathbf{O}^{(2)} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ O_{n,1}^{(1)} \mathbf{O}^{(2)} & O_{n,2}^{(1)} \mathbf{O}^{(2)} & O_{n,3}^{(1)} \mathbf{O}^{(2)} & \dots & O_{n,n}^{(1)} \mathbf{O}^{(2)} \end{bmatrix} \quad (49b)$$

$$\mathbf{O}^{(2)} = \begin{bmatrix} O_{1,1}^{(2)} & O_{1,2}^{(2)} & O_{1,3}^{(2)} & \dots & O_{1,m}^{(2)} \\ O_{2,1}^{(2)} & O_{2,2}^{(2)} & O_{2,3}^{(2)} & \dots & O_{2,m}^{(2)} \\ O_{3,1}^{(2)} & O_{3,2}^{(2)} & O_{3,3}^{(2)} & \dots & O_{3,m}^{(2)} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ O_{m,1}^{(2)} & O_{m,2}^{(2)} & O_{m,3}^{(2)} & \dots & O_{m,m}^{(2)} \end{bmatrix} \quad (49c)$$

Note that the dimension of the product space is always the product of the dimensions of the subspaces.

In equation (43) the Liouville space was introduced. With the introduction of the concept of direct products, it is possible to give a more satisfying explanation of the mapping from Hilbert space to Liouville space. The Hilbert space operators $|i\rangle\langle j|$ can be mapped onto a Liouville space with the following basis states:

$$|i\rangle\langle j| = |ij\rangle \quad (50)$$

Clearly, a one-to-one mapping is possible. In Section 5, the use of Liouville space representations will be explored further with the introduction of superoperators.

It is common in the NMR literature to have implied direct products. For example, one might write $\hat{I}_z^{(1)} + \hat{I}_z^{(2)}$, where (1) and (2) refer to different spins. This is meant to imply $\hat{I}_z^{(1)} \otimes \hat{E}^{(2)} + \hat{E}^{(1)} \otimes \hat{I}_z^{(2)}$. Alternatively, one might encounter $\hat{I}_z \hat{I}_+$, where no direct product is implied, or $\hat{I}_+^{(1)} \hat{I}_-^{(2)}$, where we are to understand that this means $\hat{I}_+^{(1)} \otimes \hat{I}_-^{(2)}$. It is necessary to understand from the context and notation what is really meant.

3 SOME COMMONLY USED BASES

Next let us consider some examples of bases commonly used in NMR, using simple spin systems to illustrate how this formalism can be applied to nuclear spins.

3.1 The Single Spin Eigenstate Basis

A single isolated spin- $\frac{1}{2}$ nucleus has two energy eigenstates. They are commonly represented as $|\alpha\rangle$ and $|\beta\rangle$; however, since this notation is applicable only for spin- $\frac{1}{2}$, we shall also use the notation $|\frac{1}{2}\rangle$ and $|\frac{-1}{2}\rangle$, respectively, where each state is labelled by its $\hat{I}_z$ eigenvalue (this will be discussed in more detail below). It is assumed that these states are orthonormal. Using equation (17a), we can write the Hilbert space representation of the basis states as

$$\left. \begin{aligned} |\alpha\rangle = |\frac{1}{2}\rangle &\rightarrow \begin{bmatrix} \langle\alpha|\alpha\rangle \\ \langle\beta|\alpha\rangle \end{bmatrix} = \begin{bmatrix} 1 \\ 0 \end{bmatrix} \\ |\beta\rangle = |\frac{-1}{2}\rangle &\rightarrow \begin{bmatrix} \langle\alpha|\beta\rangle \\ \langle\beta|\beta\rangle \end{bmatrix} = \begin{bmatrix} 0 \\ 1 \end{bmatrix} \end{aligned} \right\} \quad (51)$$

The corresponding Hilbert space representation of the basis operators can be obtained most easily using equation (36) to write

$$\left. \begin{aligned} \hat{U}_1 = |\alpha\rangle\langle\alpha| &\rightarrow \begin{bmatrix} 1 \\ 0 \end{bmatrix} \begin{bmatrix} 1 & 0 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \\ \hat{U}_2 = |\alpha\rangle\langle\beta| &\rightarrow \begin{bmatrix} 1 \\ 0 \end{bmatrix} \begin{bmatrix} 0 & 1 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix} \\ \hat{U}_3 = |\beta\rangle\langle\alpha| &\rightarrow \begin{bmatrix} 0 \\ 1 \end{bmatrix} \begin{bmatrix} 1 & 0 \end{bmatrix} = \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix} \\ \hat{U}_4 = |\beta\rangle\langle\beta| &\rightarrow \begin{bmatrix} 0 \\ 1 \end{bmatrix} \begin{bmatrix} 0 & 1 \end{bmatrix} = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix} \end{aligned} \right\} \quad (52)$$

It is easily verified that these matrices satisfy the orthonormality conditions by comparing with equation (39) for all pairs.

For spins with a higher angular momentum quantum number, the bases are similar but with higher dimension. For example, a spin-1 nucleus, like ^2H , has three eigenstates

and nine basis operators. Representations of basis states and operators for any nucleus can be obtained just as above knowing only the number of eigenstates and assuming that they are orthonormal.

3.2 The Basis Derived from Direct Products of Single Spin Bases

When the system of interest includes more than one spin, a direct product of single spin bases described in the previous section (one set corresponding to the correct spin for each nucleus) yields a basis for the combined system. The first state and the first operator for two spin- $\frac{1}{2}$ nuclei, for example, would be

$$\left. \begin{aligned} |\alpha\rangle \otimes |\alpha\rangle = |\alpha\alpha\rangle &\rightarrow \begin{bmatrix} 1 \\ 0 \end{bmatrix} \otimes \begin{bmatrix} 1 \\ 0 \end{bmatrix} \\ &= \begin{bmatrix} 1 \begin{bmatrix} 1 \\ 0 \end{bmatrix} \\ 0 \begin{bmatrix} 1 \\ 0 \end{bmatrix} \end{bmatrix} = \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \end{bmatrix} \\ \hat{U}_1 \otimes \hat{V}_1 &\rightarrow \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \otimes \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} = \begin{bmatrix} 1 \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} & 0 \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \\ 0 \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} & 0 \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \end{bmatrix} \\ &= \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \end{aligned} \right\} \quad (53)$$

The other 3 basis states and 15 operators are composed in the same fashion using all the pairs of single spin matrices.

3.3 The Basis Derived from the Eigenstates of the Hamiltonian

The states given in equation (51) for a single spin $\frac{1}{2}$ are the eigenstates of the Hamiltonian, but for two identical spin- $\frac{1}{2}$ nuclei (an A_2 spin system), the eigenstates are

$$\left. \begin{aligned} |A_2, 1\rangle = |\alpha\alpha\rangle &\rightarrow \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \end{bmatrix} \\ |A_2, 2\rangle = \sqrt{\frac{1}{2}}(|\alpha\beta\rangle + |\beta\alpha\rangle) &\rightarrow \begin{bmatrix} 0 \\ \sqrt{\frac{1}{2}} \\ \sqrt{\frac{1}{2}} \\ 0 \end{bmatrix} \\ |A_2, 3\rangle = \sqrt{\frac{1}{2}}(|\alpha\beta\rangle - |\beta\alpha\rangle) &\rightarrow \begin{bmatrix} 0 \\ \sqrt{\frac{1}{2}} \\ -\sqrt{\frac{1}{2}} \\ 0 \end{bmatrix} \\ |A_2, 4\rangle = |\beta\beta\rangle &\rightarrow \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \end{bmatrix} \end{aligned} \right\} \quad (54)$$

These equations show a representation of the eigenstates in the basis of the spin product states. Assembling these vectors into a unitary matrix according to equation (22a) gives the following transformation matrix from the spin product basis to the eigenbasis:

$$\mathbf{U} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \sqrt{\frac{1}{2}} & \sqrt{\frac{1}{2}} & 0 \\ 0 & \sqrt{\frac{1}{2}} & -\sqrt{\frac{1}{2}} & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (55)$$

It is easily verified that $\mathbf{U}\mathbf{U}^\dagger = \mathbf{U}\mathbf{U}^{-1} = \mathbf{E}$. Applying this transformation to the spin product states or operators yields the desired eigenstate basis for the Hilbert space representation or the Liouville space representation, respectively.

3.4 The Angular Momentum Operator Basis

For a single spin- $\frac{1}{2}$ nucleus, the components of the angular momentum vector operator $\hat{\mathbf{I}} = \{\hat{I}_x, \hat{I}_y, \hat{I}_z\}$ augmented by the identity operator $\hat{E}$ are a complete basis. For a development of the angular momentum operators from first principles, the reader is referred to the standard texts.^{6,7,10} We shall be content to define them according to their effect on the basis states as in equation (5). For any spin- I nucleus there are $2I + 1$ quantum states $|m\rangle$ such that

$$\left. \begin{aligned} \hat{I}_x|m\rangle &= \frac{1}{2} \{ [I(I+1) - m(m+1)]^{1/2} |m+1\rangle \\ &\quad + [I(I+1) - m(m-1)]^{1/2} |m-1\rangle \} \\ \hat{I}_y|m\rangle &= \frac{1}{2i} \{ [I(I+1) - m(m+1)]^{1/2} |m+1\rangle \\ &\quad - [I(I+1) - m(m-1)]^{1/2} |m-1\rangle \} \\ \hat{I}_z|m\rangle &= m|m\rangle \end{aligned} \right\} \quad (56)$$

The eigenvalue m ranges in integer steps such that $-I \leq m \leq I$. For spin- $\frac{1}{2}$, using the $\{|\frac{1}{2}\rangle, |-\frac{1}{2}\rangle\}$ basis, the angular momentum operators and their representations are

$$\begin{aligned} \hat{I}_x &\rightarrow \frac{1}{2} \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, & \hat{I}_y &\rightarrow \frac{1}{2i} \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix} \\ \hat{I}_z &\rightarrow \frac{1}{2} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}, & \hat{E} &\rightarrow \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \end{aligned} \quad (57)$$

It is easily verified that these operators are orthogonal but not normalized using equation (39). Normalization can easily be achieved by multiplying by the appropriate constants to satisfy equation (39); this yields the desired basis for spin- $\frac{1}{2}$:

$$\left. \begin{aligned} \hat{U}_1 &= \frac{1}{\sqrt{2}} \hat{E} \rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \\ \hat{U}_2 &= \sqrt{2} \hat{I}_z \rightarrow \frac{\sqrt{2}}{2} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \\ \hat{U}_3 &= \sqrt{2} \hat{I}_x \rightarrow \frac{\sqrt{2}}{2} \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \\ \hat{U}_4 &= \sqrt{2} \hat{I}_y \rightarrow \frac{\sqrt{2}}{2i} \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix} \end{aligned} \right\} \quad (58)$$

For a spin-1 nucleus, using equation (56), the angular momentum operators are

$$\left. \begin{aligned} \hat{I}_x &\rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix}, & \hat{I}_y &\rightarrow \frac{1}{i\sqrt{2}} \begin{bmatrix} 0 & 1 & 0 \\ -1 & 0 & 1 \\ 0 & -1 & 0 \end{bmatrix} \\ \hat{I}_z &\rightarrow \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{bmatrix} \end{aligned} \right\} \quad (59)$$

However, since nine basis operators are required for spin 1, augmenting this set with $\hat{E}$ would clearly not be sufficient to produce a complete basis. However, we shall defer enumerating the other members of this basis until the next section, because the task becomes much easier once the spherical tensor operators have been introduced.

3.5 The Spherical Tensor Operator Basis

Examination of equation (56) rapidly leads one to conclude that a simpler basis might be composed including the following operators:

$$\left. \begin{aligned} \hat{I}_+|m\rangle &= [I(I+1) - m(m+1)]^{1/2} |m+1\rangle \\ \hat{I}_-|m\rangle &= [I(I+1) - m(m-1)]^{1/2} |m-1\rangle \end{aligned} \right\} \quad (60)$$

These operators are commonly called the *raising* or *step-up* and *lowering* or *step-down* operators, because they convert a given eigenket of $\hat{I}_z$ into one with the eigenvalue increased or decreased, respectively, by one. In terms of these operators, we have

$$\hat{I}_x = \frac{1}{2}(\hat{I}_+ + \hat{I}_-), \quad \hat{I}_y = \frac{1}{2i}(\hat{I}_+ - \hat{I}_-) \quad (61)$$

The inverse relationship is

$$\hat{I}_+ = \hat{I}_x + i\hat{I}_y, \quad \hat{I}_- = \hat{I}_x - i\hat{I}_y \quad (62)$$

Applying these relations to equation (57) leads to a new basis:

$$\left. \begin{aligned} \hat{I}_+ &\rightarrow \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, & \hat{I}_- &\rightarrow \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix} \\ \hat{I}_z &\rightarrow \frac{1}{2} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}, & \hat{E} &\rightarrow \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \end{aligned} \right\} \quad (63)$$

The orthonormal basis corresponding to equation (58) is given by

$$\left. \begin{aligned} \hat{U}_1 &= \hat{T}_{0,0}^{(0)} = \frac{1}{\sqrt{2}} \hat{E} \rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \\ \hat{U}_2 &= \hat{T}_{0,0}^{(1)} = \sqrt{2} \hat{I}_z \rightarrow \frac{\sqrt{2}}{2} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \\ \hat{U}_3 &= \hat{T}_{1,0}^{(1)} = -\hat{I}_+ \rightarrow \begin{bmatrix} 0 & -1 \\ 0 & 0 \end{bmatrix} \\ \hat{U}_4 &= \hat{T}_{-1,0}^{(1)} = \hat{I}_- \rightarrow \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix} \end{aligned} \right\} \quad (64)$$

The $\hat{T}_{q,j}^{(k)}$ designation for these operators is that characterizing the *irreducible spherical tensor operators*. There will be

$2k + 1$ members in a set of operators of rank k with projection q ranging from $-k$ to k in integer steps. Note that the index j is not needed here, but will come into play when more complicated spin systems are considered with more than one set of operators of a given k . In what follows, the index j will be suppressed when it is not needed. It is easily verified that this basis is orthonormal. The minus sign associated with $\hat{U}_3$ does not affect the orthonormality of the set. It is common practice to choose this ‘phase factor’ to correspond to that of the spherical harmonic functions, i.e., such that

$$\hat{T}_q^{(k)\dagger} = (-1)^q \hat{T}_{-q}^{(k)} \quad (65)$$

The operators then satisfy equation (39) in the form

$$\text{Tr}(\hat{T}_q^{(k)} \hat{T}_{q'}^{(k)\dagger}) = (-1)^q \text{Tr}(\hat{T}_q^{(k)} \hat{T}_{-q'}^{(k)}) = \delta_{kk'} \delta_{q-q'} \quad (66)$$

The defining characteristic of the irreducible spherical tensor operators is that when they are subjected to a rotation of the coordinate system, they behave like the spherical harmonic functions, i.e., they transform to linear combinations of the set such that operators of differing k or j never mix:

$$\hat{R}(\phi, \theta, \chi) \hat{T}_{q,j}^{(k)} \hat{R}^{-1}(\phi, \theta, \chi) = \sum_{q'=-k}^k D_{q'q}^{(k)}(\phi, \theta, \chi) \hat{T}_{q',j}^{(k)} \quad (67)$$

The rotation operator $\hat{R}(\phi, \theta, \chi)$ and its inverse (defined by equation (68)) transform any operator from the original coordinate system $\{x, y, z\}$ into a new one $\{x', y', z'\}$:
